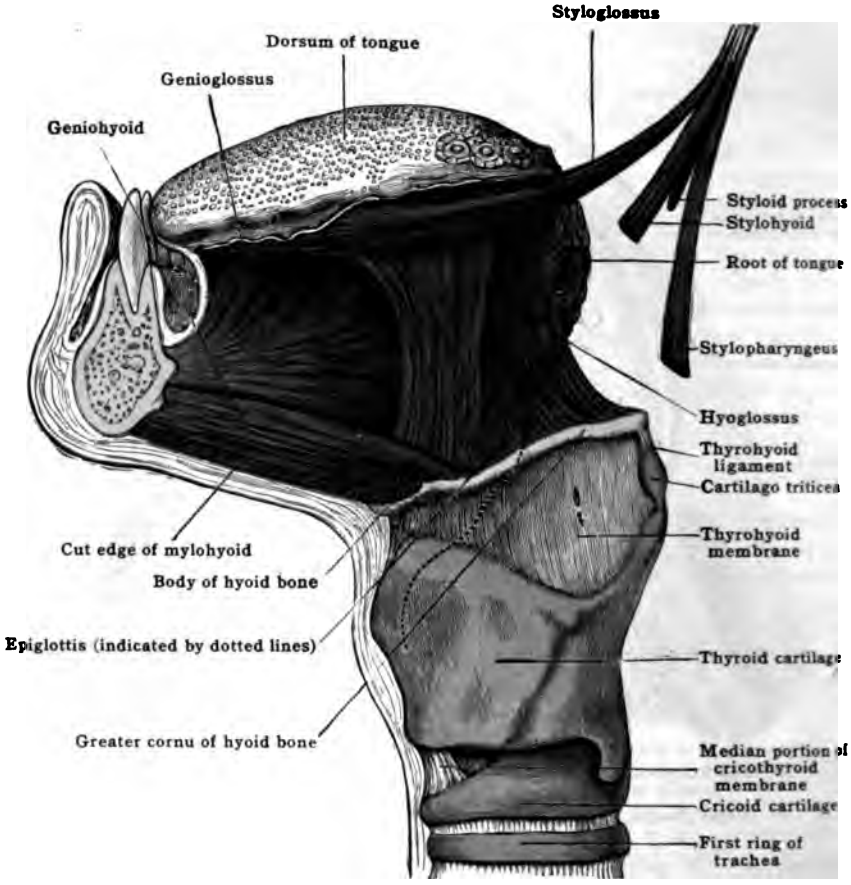
The **tongue** [lingua] is a muscular organ covered with mucous membrane and located in the floor of the mouth. It is an important organ of mastication, deglutition, taste and speech. Upon its upper surface (fig. 889) is a V-shaped groove (sulcus terminalis) indicating the division of the tongue into two parts. The larger anterior part, or *body* [corpus linguæ] belongs to the floor of the mouth, while the smaller posterior part, or *root* [radix linguæ], forms the anterior wall of the oral pharynx. The *inferior* surface [facies inferior] of the tongue is chiefly attached to the muscles of the floor of the mouth, from the hyoid bone to the mandible (fig. 884). Anteriorly and laterally, however, the inferior surface of the body is free and covered with mucosa. The superior surface of the body is called

the *dorsum*. It is separated from the inferior surface by the *lateral margins*, which meet anteriorly at the *tip* [apex linguæ].

The dorsum of the tongue usually presents a slight *median groove* [sulcus medianus linguæ]. Its posterior end corresponds to a small pit of variable depth, the *foramen cecum*, which is placed at the apex of the V-shaped *terminal sulcus*. The dorsum of the body has a characteristic rough appearance due to numerous small projections, the *lingual papillæ*.

Lingual papillæ.—Five or six varieties of papillæ are distinguished, between which intermediate forms occur. The *conical* [papillæ conices] and *thread-like* [papillæ filiformes] are most numerous, and are arranged more or less distinctly in rows parallel with the terminal

FIG. 881.—LEFT SIDE OF THE TONGUE, WITH ITS MUSCLES, ETC.



sulcus (fig. 882). They are best developed toward the midline of the dorsum in its posterior part. As shown in vertical section (fig. 882), each papilla consists of an axial core of vascular fibrous tissue (from the lamina propria) often beset with smaller secondary papillæ. The stratified squamous epithelial covering often presents numerous thread-like prolongations from the apex of the papilla. The papillæ vary from 1 to 3 mm. in length.

The **fungiform** ('toadstool-shaped') papillæ are somewhat similar to the conical in structure, but larger and more prominent, with an expanded free portion and a slightly constricted stalk of attachment. They are relatively few in number and are scattered irregularly over the dorsum, being most numerous near the margins (fig. 889). They are easily distinguished in life by their larger size and reddish color. A smaller, flattened variety of the fungiform is sometimes called the *lenticular* ('lens-shaped') papillæ. (This term, however, is applied by Toldt to certain small rounded elevations with underlying lymphatic nodules in the mucosa of the root of the tongue.)

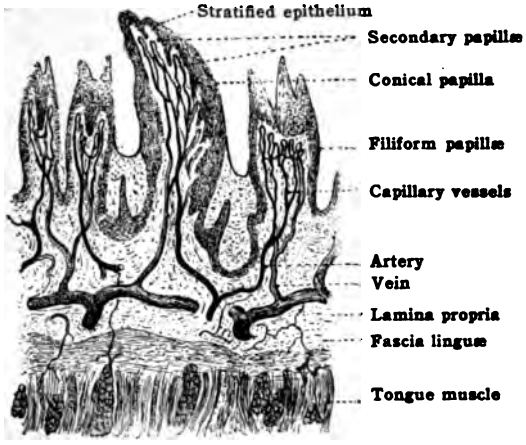
The **vallate** (circumvallate) papillæ [papillæ vallatæ], usually seven to eleven in number, are conspicuous and arranged in a V-shaped line parallel with and slightly anterior to the sulcus terminalis, (fig. 889). They are, as a rule, shaped like short cylinders, 1 to 2 mm. in width, and somewhat less in height. As is shown in section (fig. 883), each is surrounded by a trench or fossa, into the bottom of which open ducts of the serous glands of von Ebner. On the sides of the fossæ are the *taste-buds*, as described in the section on SENSE ORGANS.

The **foliate** papillæ are represented by a few (five to eight) parallel transverse or vertical folds of mucosa, along the margins of the tongue just anterior to the glossopalatine arch on each side (fig. 889). They are variable in size and sometimes rudimentary. In structure they somewhat resemble the vallate papillæ (though of different form), their walls being studded with taste-buds.

The free **inferior surface** of the tongue (fig. 884) is covered by a thin smooth mucosa. In the median line is a prominent fold, the *frenulum*, which connects the tongue with the mandible and the floor of the mouth. On each side of the inferior surface, an irregular, variable, fringed fold, the *plica fimbriata*, extends from near the apex backward approximately parallel with the lateral margin of the tongue (fig. 884). Between the frenulum and the plicæ fimbriatæ, the lingual (ranine) veins are visible on each side beneath the mucosa.

The **root** (or base) of the tongue [radix linguæ] belongs to the pharynx, but is here included with the mouth for convenience of description. Its free surface is directed posteriorly, and represents the continuation of the dorsum linguæ (fig. 881). Laterally it is continuous with the region of the palatine tonsils. Inferiorly it extends to the epiglottis, with which it is connected by a median and two lateral folds, between which are the depressions known as the *valleculæ*. The

FIG. 882.—SECTION OF LINGUAL PAPILLÆ. × 20. (From Toldt's Atlas.)



mucosa over the root of the tongue is irregular and warty in appearance due to the projections of the underlying nodular masses of lymphoid tissue, the *lingual follicles*. A *crypt* or tubular pocket of surface epithelium usually dips down into each of these follicles, as seen in surface view, and shown in section (fig. 885). The follicles vary from 34 to 102 in number, the average being 66 (Ostman), and are somewhat irregular in size and form. They are often arranged in more or less distinct longitudinal rows, with corresponding folds of the mucosa (Jurisch). The lingual follicles are collectively designated as the **lingual tonsil** [tonsilla lingualis]. Between the lingual follicles and around the periphery of the lingual tonsil there are found smaller ordinary lymphoid nodules (without crypts) and indefinite masses of lymphoid tissue. The sulcus terminalis forms a fairly sharp boundary between the lymphoid mucosa of the root and the papillated mucosa of the body of the tongue (fig. 889).

Glands.—The glands of the tongue are of three types—mucous, serous and mixed. The most numerous are those of the **mucous** type, which are typical for the mouth cavity in general and resemble those already described in the lips, cheeks and palate. They are spread over the entire surface of the root of the tongue, in the spaces between the lingual follicles, usually opening upon the surface but in many cases into the crypts. Anteriorly, they extend a short distance along the posterior portion of the lateral margin of the tongue, and also occupy small areas in and near the midline in front of the vallate papillæ.

In the immediate region of the vallate papillæ, and in the small lateral areas corresponding to the foliate papillæ (i. e., in the regions of the taste-buds), the mucous glands are displaced by the **serous** glands (of von Ebner), which have a watery secretion (fig. 883). Finally, on the inferior surface of the tongue, on either side of the frenulum near the apex, are the **anterior lingual glands** (glands of Nuhn or Blandin). Each is about 15 mm. in length, and is composed of a group of racemose glands with three or four very small ducts opening on the surface of the

tongue near the plica fimbriata. The anterior lingual glands are deeply placed and are covered not only by the mucosa, but also by some of the longitudinal muscle-fibers (inferior longitudinal and styloglossus). This gland is of the mixed type, though chiefly mucous.

FIG. 883.—VERTICAL SECTION OF A HUMAN VALLATE PAPILLA WITH LINGUAL GLANDS. × 25. (Lewis and Stöhr.)

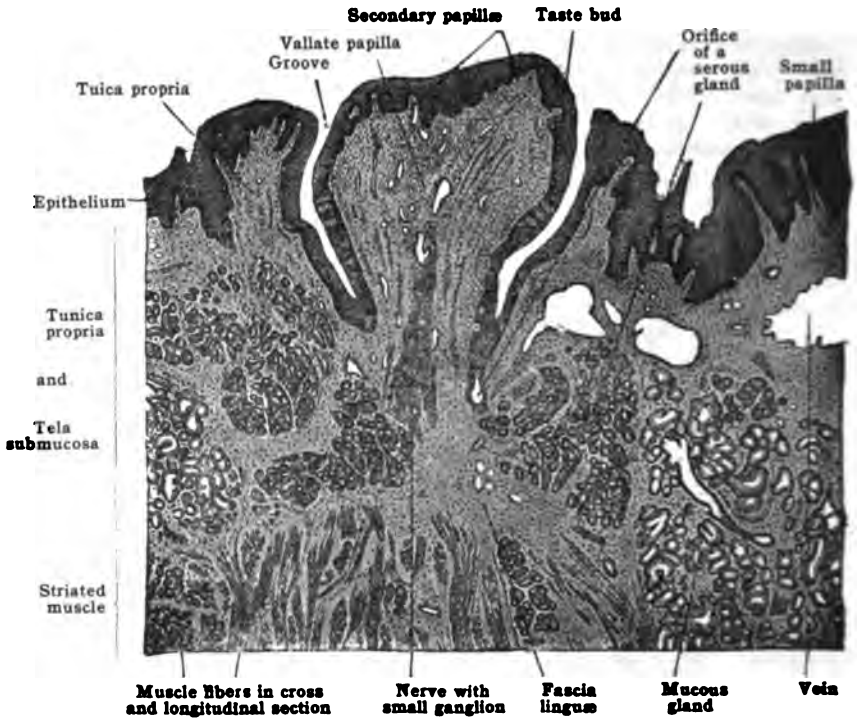


FIG. 884.—INFERIOR SURFACE OF THE TONGUE. (Modified from Spalteholz.)

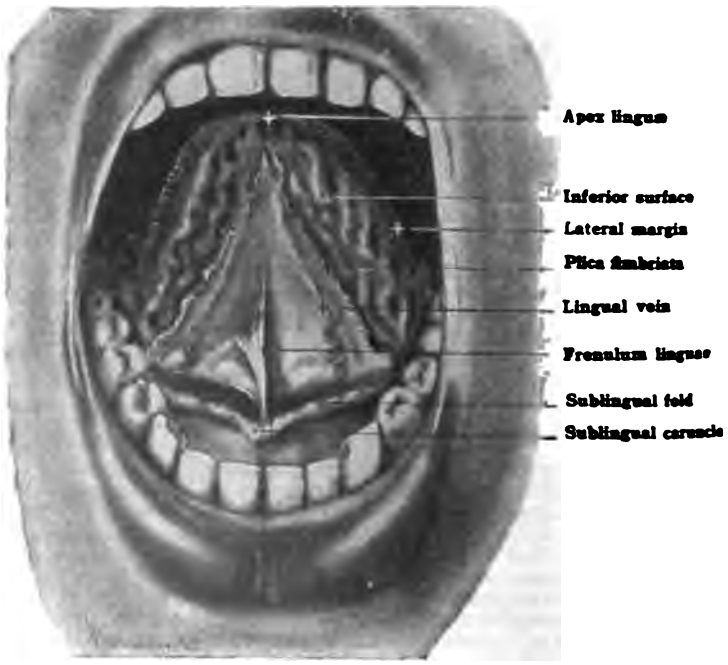
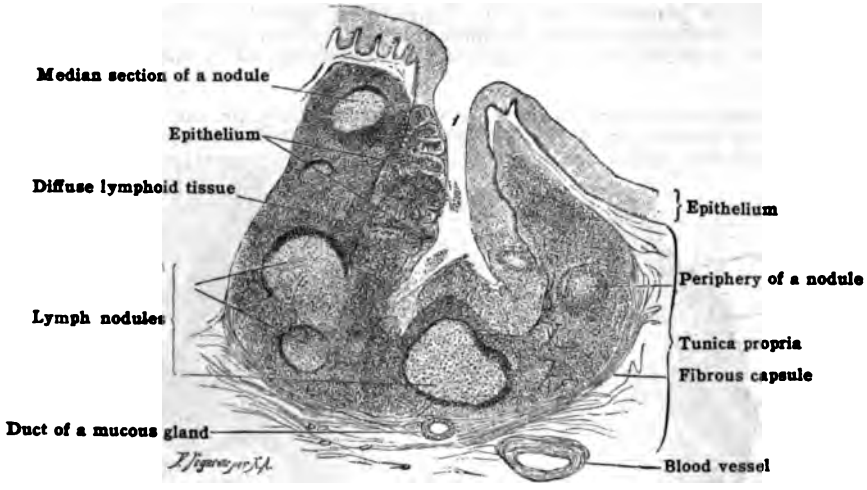


Muscles of the tongue.—A layer of fibrous connective tissue, the **lingual septum**, separates the halves of the tongue, extending in the median plane from the apex to the root, where it is attached below to the hyoid bone. The muscles of the tongue are classified as extrinsic and

insic. The **extrinsic muscles** (fig. 881) extend into the tongue from without. They are hyoglossus, chondroglossus, genioglossus, styloglossus, and glossopalatinus (palatoglossus), of which are described elsewhere (see Section V).

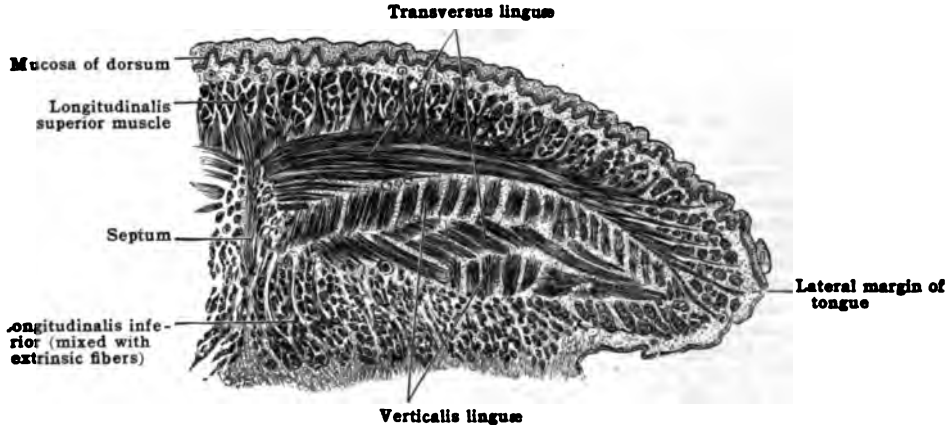
The intrinsic muscles.—The **longitudinalis superior** (fig. 886) is a superficial longitudinal atum extending from the base to the apex of the tongue, immediately beneath the mucosa the dorsum, to which many of its fibers are attached. The **longitudinalis inferior** (fig. 886) composed of two muscle-bands extending from base to apex on the inferior surface of the

FIG. 885.—FROM A SECTION OF THE LINGUAL TONSIL OF AN ADULT MAN. × 20. 1. Pit crypt) containing leucocytes which have infiltrated its epithelium on the left side; that on the ght is almost intact. (Lewis and Stöhr.)



ıgue, and is situated between the hyoglossus and the genioglossus, some of its fibers near e apex mixing with the styloglossus, while posteriorly some are attached to the hyoid bone. The **ınsversus linguæ** (fig. 886) consists of fibers which pass transversely, and is situated between e superior and inferior longitudinal muscles. The fibers arise from, or pass through, the sep- m linguæ, and are attached to the mucosa of the dorsum and lateral margins of the tongue. ıe **verticalis linguæ** (fig. 886) is composed of fibers which pass from the mucosa of the dorsum the mucosa of the inferior surface of the tongue, interlacing with those of the other intrinsic d extrinsic muscles.

G. 886.—TRANSVERSE SECTION THROUGH THE LEFT HALF OF THE TONGUE. (Magnified.) (From a preparation by Mr. J. Pollard, Middlesex Hospital Museum.)



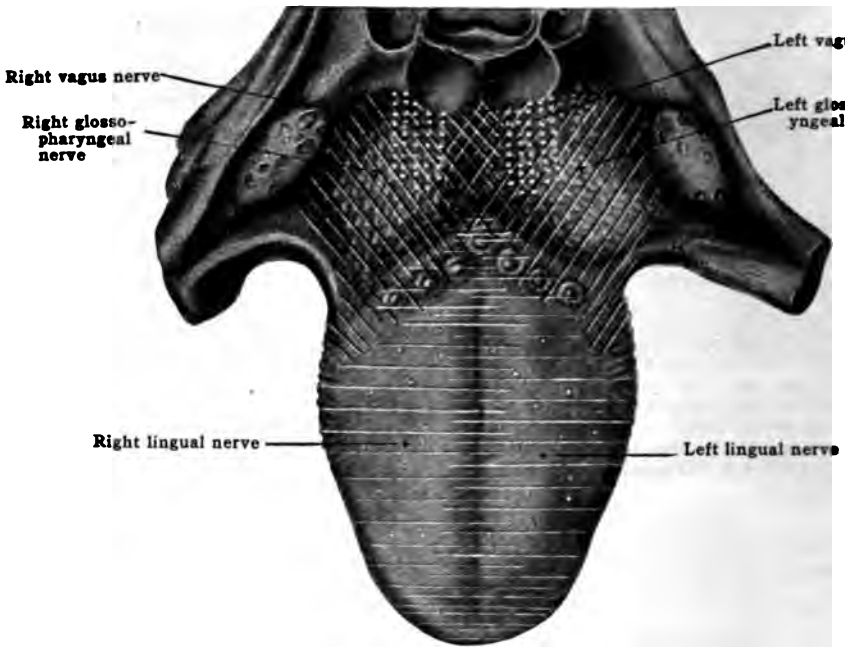
Vessels and nerves.—The **lingual arteries** furnish the principal blood-supply. The **lingual ins** carry the blood from the tongue to the internal jugular. The **lymphatics** form a network the lamina propria, connected with a deeper network in the submucosa. The latter network rms plexuses around the lingual follicles. The efferent lymph-vessels from the tongue empty iefly into the superior deep cervical lymph-nodes. (For details concerning the blood- and mph-vessels, see Sections VI and VII.) **The nerves** are motor and sensory. The **hypoglossal rve** supplies the intrinsic and all the extrinsic muscles of the tongue except the glossopalatinus alatoglossus), which is supplied from the pharyngeal plexus. The sensory nerves (fig. 887)

are:—the **lingual nerve**, a branch of the mandibular division of the trigeminus, which, after joining with the chorda tympani from the facial, is distributed to the anterior two-thirds of the tongue and represents the nerve of touch; the **lingual branches of the glossopharyngeal** (nerve of taste), which are distributed to the root of the tongue, including also the vallate and foliate papillæ; and **the superior laryngeal branch of the vagus**, which supplies a small area near the epiglottis.

Development.—The body of the tongue (anterior to the sulcus terminalis) is derived from the ventral region of the mandibular arch, and its epithelium is derived from the ectoderm of the oral sinus. The root of the tongue is covered with entodermal epithelium of the oral pharynx. For details concerning the development of the tongue, see p. 41.

Variations.—Of the manifold variations in the structure of the tongue, some have already been mentioned. Additional mucous glands sometimes occur along the margin of the tongue (completing Oppel's 'glandular ring'). In 'tongue-tied' individuals, the frenulum is abnormally short. A *forked* tongue (normal in some animals) is a rare congenital anomaly. Another rare variation is the so-called *'hairy'* tongue, due to hypertrophy of the filiform papillæ. While

FIG. 887.—SCHEMATIC REPRESENTATION OF THE DISTRIBUTION OF THE SENSORY NERVES IN THE MUCOUS MEMBRANE OF THE TONGUE. Areas of distribution according to R. Zander. When dotted area indicates vagus; oblique lines, glossopharyngeal; horizontal lines lingual.



the V-shaped arrangement of the vallate papillæ is typical, the Y-form (two to four papillæ in the median line forming the stem of the Y) is nearly as frequent. Indeed, in some of the colored races the latter type seems to predominate. The sulcus terminalis and foramen cecum are often indistinct and sometimes absent.

Comparative.—The tongue of fishes and lower amphibia contains neither glands nor intrinsic musculature. Among higher vertebrates, the tongue varies exceedingly in form and structure, but always contains intrinsic musculature and mucous glands. The latter primitively form a ring around the margin and root of the tongue (Oppel). The serous glands occur only in mammals, and are associated closely with the papillæ bearing taste-buds.

The plica fimbriata in man is homologous with the 'sublingua' of lower mammals. According to Gegenbaur, the 'sublingua' represents the entire primitive vertebrate tongue, but this view is opposed by Oppel. Among various mammals, the number of vallate papillæ varies from one to thirty, but the V- or Y-arrangement is typical. The region of the foliate papillæ ('marginal organ') is typical for mammals, and is much better developed in some (e. g., rabbit) than in man. The mucosa of the root of the tongue is always different from that of the body. The lingual papillæ are especially well developed in the tongue of carnivora.

THE SALIVARY GLANDS

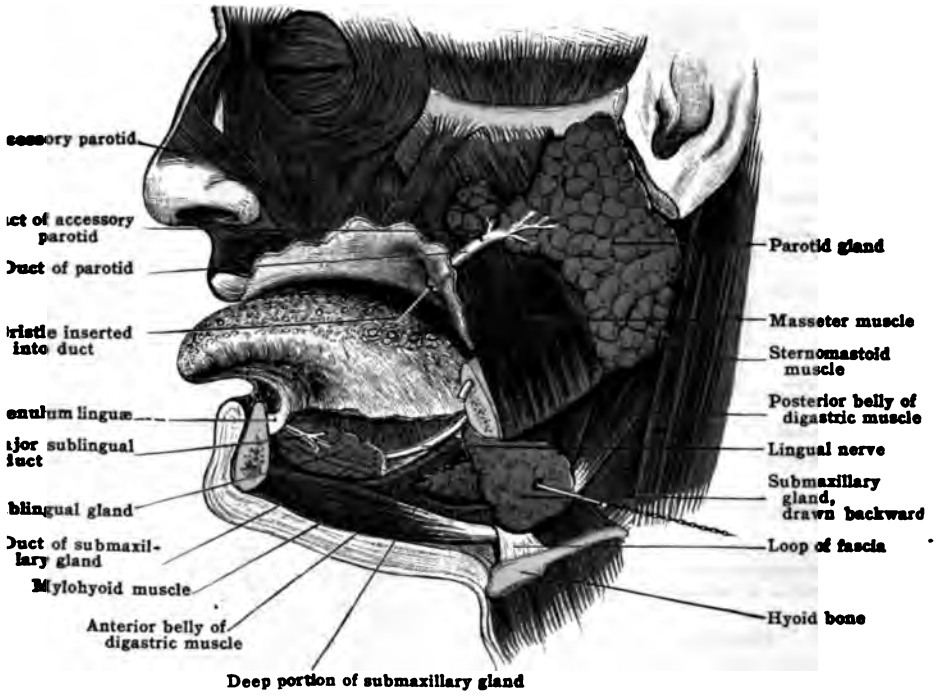
Numerous glands—labial, buccal, palatine and lingual—have already been mentioned, which pour their secretions into the mouth cavity. In addition to these there are three larger pairs, the salivary glands proper. They include the parotid, the submaxillary, and the sublingual (the latter really a group of glands).

THE PAROTID GLAND

The parotid gland [glandula parotis] is the largest of the salivary glands, ying from 15 to 30 gm. in weight. It is located below and in front of the ear the retromandibular fossa (fig. 888), extending from the zygomatic arch above the angle of the mandible below.

Form and relations.—The parotid is somewhat prismatic or wedge-shaped gs. 888, 889), with three surfaces and three borders or angles. The *lateral* sur- e is covered by skin and superficial fascia, and in its lower part by the platysma. e *anterior* (anteromedial) surface overlaps the masseter and extends medial- rd in contact with the posterior border of the mandibular ramus and with the sterior aspect of the internal pterygoid muscle. An irregular 'pterygoid lobe' y extend forward. The *posterior* (posteromedial) surface is in contact with

FIG. 888.—THE SALIVARY GLANDS.



sternomastoid muscle laterally, and with the styloid process and associated scles medially. Between the sternomastoid and styloid process it touches the sterior belly of the digastric, and is in relation with the internal carotid and gular vessels. The upper part of the posterior surface is in contact with the stoid process. The various structures in contact with the parotid gland often ke more or less distinct grooves upon its posterior and anterior surfaces.

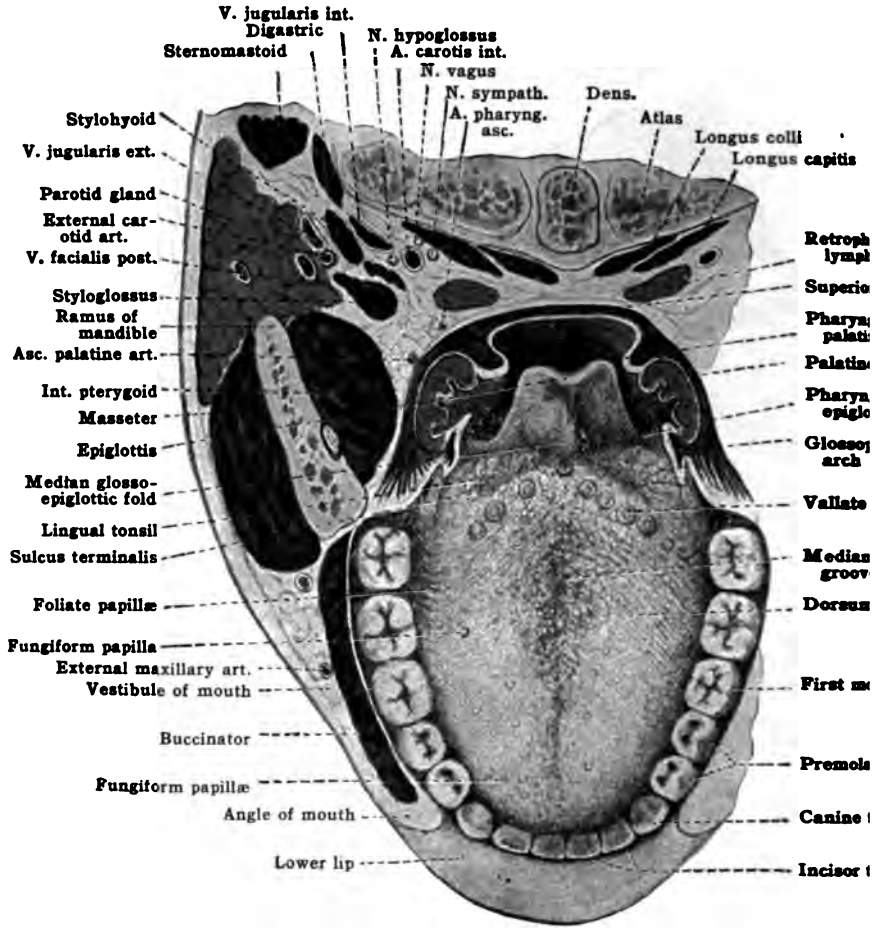
Borders.—The *anterior* border usually extends from below obliquely upward d forward so as to give the whole superficial surface a triangular appearance. ar the upper end of the anterior border, the parotid duct leaves the gland, and t above this there is usually a small separate *accessory lobe* [gl. parotis acces- ia], of variable form and size. The branches of the facial nerve also emerge m the anterior border. The *posterior* border extends along the anterior aspect the sternomastoid muscle up to the mastoid process. The *medial* border deeply placed (at the junction of the anterior and posterior surfaces), and proaches the wall of the pharynx. The medial border forms the apex of the dge-shaped parotid mass, and is termed the *processus retromandibularis*.

The *upper extremity* of the parotid sends a process into the posterior part of manibular fossa, behind the condyle of the mandible, and is related with the ernal auditory meatus. From the upper extremity emerge the superficial

temporal vessels and the auriculotemporal nerve. The *lower extremity* is rated by the stylomandibular ligament from the posterior end of the submax gland.

Fascia.—As shown in fig. 890, the parotid gland is enclosed in a sheath (called the fascia or aponeurosis) derived from the deep fascia of the neighborhood. The su layer of the sheath covers the lateral surface of the gland, while the deep layers cover the anterior and posterior surfaces of the gland. The sheath is very feeble or deficient medial angle. The superficial and the deep layers of the parotid sheath unite below to thick fascial band (stylomandibular ligament) extending from the angle of the mandible tip of the styloid process.

FIG. 889.—HORIZONTAL SECTION THROUGH HEAD AT LEVEL OF RIMA ORIS. (After modified.)



Contents.—Within the sheath, the parotid gland is in intimate relation with i important structures. Extending along the medial border, and partly embedded in t is the external carotid artery, dividing above into the superficial temporal and internal (including the origins of the deep auricular and transverse facial); and the poster (temporomaxillary) vein and branches. The auriculotemporal nerve passes through t part of the gland, while the facial nerve passes through it at a lower level, dividin temporofacial and cervicofacial divisions. Grégoire (Jour. de l'anat., etc. T. 48, 1 McWhorter (Anat. Rec., Vol. 12, 1917) have shown that the parotid is fundamentally into two lobes, superficial and deep, between which lie the principal branches of the fac Finally, there are embedded in the gland two or three deep lymphatic nodes, whic lymphatic vessels from the external auditory meatus, the soft palate and the posterio the nasal fossa; and several superficial nodes, which receive lymphatic vessels from th eyebrows and eyelids, cheek and auricle.

Structure.—The parotid is a racemose gland of the serous type.

Duct, vessels and nerves.—The parotid duct (Stenson's) issues from the anterio of the gland, crosses the masseter a finger's breadth below the zygoma, and turns medialward round the anterior border. It penetrates the fat of the cheek and t of the buccinator muscle, between which and the mucous membrane it ru

nce before it terminates, sometimes on the summit of a little papilla, by a minute
ıis opening is placed opposite the crown of the second upper molar tooth. The duct
: by numerous branches, which converge toward the anterior border of the gland,
's in its passage across the masseter the duct of the accessory parotid gland. The
ɔut the size of a crow-quill; length about 35 to 40 mm., diameter 3 mm. The wall
; is thick and tough, and consists of fibrous tissue intermixed with smooth muscle-

:eries are derived from those lying in the gland substance and from the posterior
rtery. The veins terminate in the posterior facial (temporomaxillary) trunk.
rves.—The parotid gland receives its secretory fibers from the otic ganglion, con-
ıulses from the glossopharyngeal via the lesser petrosal and the auriculotemporal;
supply through branches of the fifth nerve; and its sympathetic supply from the

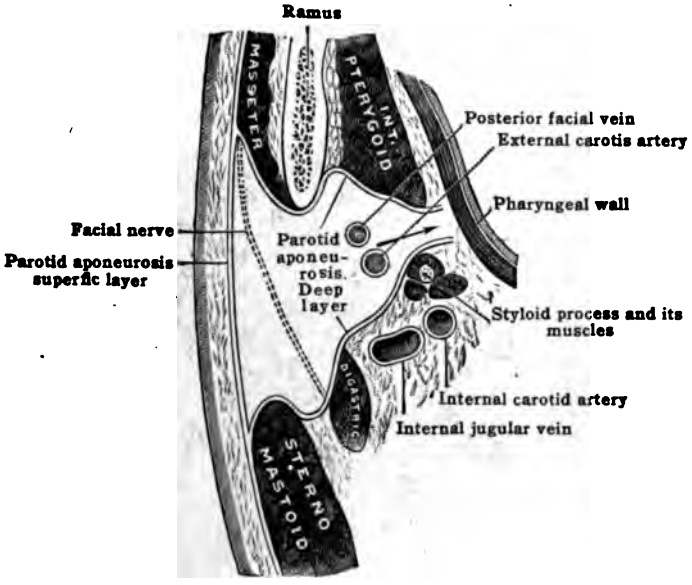
TIONS. Arrow indicates opening in sheath. (From Woolsey after Testut.)



xus. The **lymphatics** from the parotid gland terminate in the superficial and deep
nds, and especially in the deeper group of parotid nodes embedded in the substance
d.
ns.—The parotid is quite variable in size and in the form of its various processes,
of the accessory lobe, as already mentioned. The lobulations are less distinct in
Rarely the parotid is confined to the masseteric region, the retromandibular fossa
with a fatty tissue enclosing the vessels and nerves normally found with the gland.

THE SUBMAXILLARY GLAND

ıbmaxillary gland [glandula submaxillaris] weighs 7 to 10 grams, and is of
form and size of a flattened walnut. It consists of a chief or superficial
a smaller deep process. The chief portion is located in the digastric
ınd presents three surfaces—superficial, deep and lateral (figs. 875, 891).
:es.—The *superficial* (inferolateral) surface is covered by skin, superficial
ia, platysma and deep fascia (which forms an incomplete capsule around
). It is crossed by the anterior facial vein and by cervical branches of
nerve. Several lymphatic glands, which receive vessels from the ante-
l region, lie upon or embedded in this surface.
ıteral surface is the smallest of the three. It is in contact with the sub-
fossa of the medial surface of the mandible, and with the lower part of
nal pterygoid muscle. The posterior aspect of the gland is deeply
ɣ the external maxillary (facial) artery and is separated from the parotid
the stylomandibular ligament. The *deep* (mediosuperior) surface is
t with the lower surface of the mylohyoid, and behind this with the hyo-
ıtylohyoid and posterior belly of the digastric. Between this surface
mylohyoid muscle are the mylohyoid nerve and artery and the sub-
'tery.

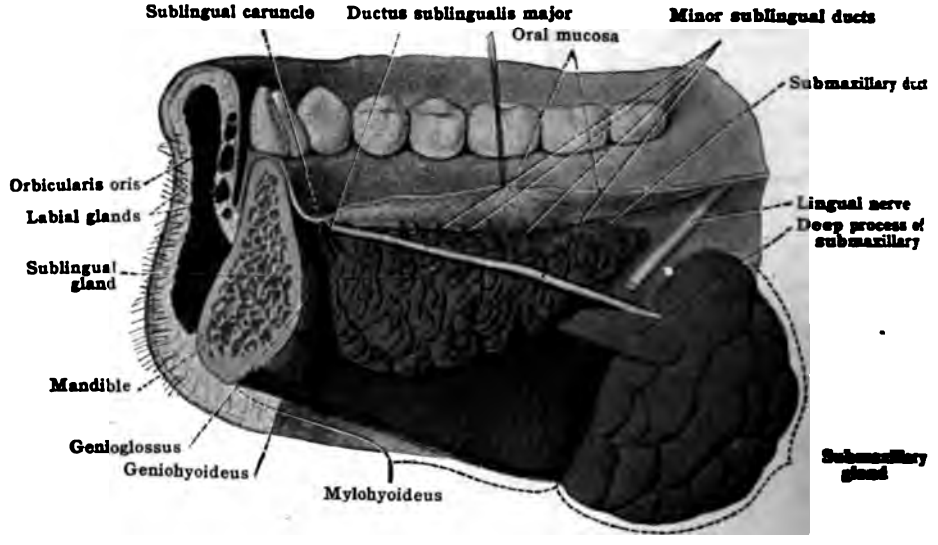
The **deep process** (fig. 891) is a tongue-like extension which passes from the deep surface of the submaxillary gland around the posterior border of the mylohyoid muscle, and extends forward in company with the duct, under cover of (above) the mylohyoid, and in relation with the hyoglossus and genioglossus muscles. At its commencement, the deep process lies just below the submaxillary ganglion.

Structure.—The submaxillary is a racemose gland belonging to the mixed type, some of the acini being serous, others mucous.

The **submaxillary (Wharton's) duct** springs from the deep surface of the superficial part of the gland associated with the deep process; it passes forward and inward and opens by a small orifice on the summit of a papilla [caruncula sublingualis] by the side of the frenulum of the tongue. It is crossed superficially by the lingual nerve. It lies at first between the mylohyoid and hyoglossus; next, between the mylohyoid and genioglossus; and lastly, under cover of the mucous membrane of the mouth, between the genioglossus and the sublingual gland. The duct is about 5 cm. in length, and has comparatively thin walls.

Vessels and nerves.—The **arteries** to the gland are derived from the external maxillary (facial) and lingual, and they are accompanied by *veins* joining the anterior facial.

FIG. 891.—MEDIAL VIEW OF THE SUBMAXILLARY AND SUBLINGUAL GLANDS. (Sobotta–McMurrich's Atlas.)



The **nerves.**—The submaxillary gland receives its secretory fibers from numerous small sympathetic ganglia situated on the submaxillary duct and in the hilus of the gland, these conveying impulses from the chorda tympani; its sensory branches probably come from the geniculate ganglion, and its sympathetic branches from the cervical sympathetic.

Variations.—Absence of the gland is a rare anomaly. A case is recorded (Turner) where the submaxillary was placed entirely under cover of the mylohyoid, being closely associated with the sublingual gland.

THE SUBLINGUAL GLAND

The **sublingual gland** [gl. sublingualis]—the smallest of the salivary glands (2 to 3 gm.) is in reality a group of glands forming an elongated mass in the floor of the mouth under the tongue (fig. 875). *Above*, it forms a distinct ridge, covered by a fold of mucosa (plica sublingualis) upon which its ducts open (fig. 891). It is flattened from side to side, its *lower* border resting upon the upper surface of the mylohyoid, its *lateral* surface in contact with the sublingual fossa of the mandible, and its *medial* surface with the geniohyoid, geniohyoglossus, lingual nerve, deep lingual artery and submaxillary duct (fig. 888). *Anteriorly* it touches its fellow of the opposite side, while *posteriorly* it is often related with the deep process of the submaxillary gland. It has no distinct capsule, thus differing from the submaxillary and parotid glands. In *structure*, it is a racemose mixed gland, but predominantly mucous.

Ducts. The *minor sublingual ducts* [ductus sublinguales minores], ducts of Rivinus, vary from five to fifteen or more in number, and open on minute papillæ along the crest of the plica sublingualis (fig. 884). The anterior portion of the gland often forms a *major* (*Bartholin's*) *duct* [ductus sublingualis major] which opens alongside the submaxillary duct on the *caruncula sublingualis* (figs. 884, 891).

Vessels and nerves.—The *arteries* are derived from the sublingual and submental, with corresponding *veins*. The *lymphatics* are tributaries of the superior deep cervical nodes.

Nerves.—The sublingual glands receive their secretory fibers from the submaxillary and associated sympathetic ganglia, conveying impulses from the chorda tympani; sympathetic branches come from the cervical sympathetic and sensory fibers probably from the geniculate ganglion, although this question needs further investigation.

Development of the salivary glands.—The salivary glands appear early as buds from the ectodermal epithelium of the oral sinus. For details, see p. 41.

Variations.—The duct of Bartholin is present in about half of the cases, and the corresponding anterior part of the gland may be more or less separate [gl. sublingualis major]. The number of ducts may reach thirty (Tillaux). Rarely processes from the gland may penetrate the mylohyoid, appearing on its lower surface in one or more places (Moustin). Most of the variations in this and the other salivary glands are due to developmental irregularities.

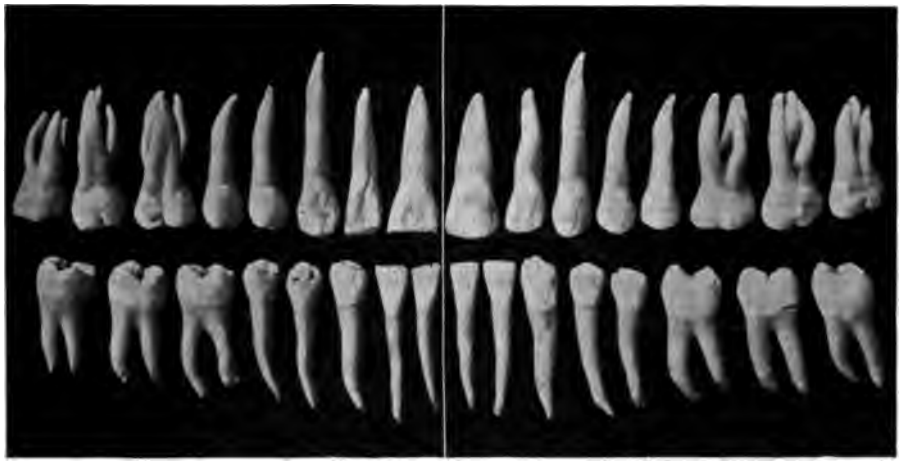
Comparative.—Oral glands are usually absent in the lower aquatic vertebrates. Mucous glands occur in all terrestrial vertebrates, but true salivary (digestive) glands appear only in mammals. Although great variations occur in the different species of mammals, those in man (excepting the anterior lingual) are typical for the order. The sublingual gland, however, often occurs as two separate glands, corresponding to the sublingualis major and minor. The parotid gland apparently has no representative in forms below mammals. In some mammals (e. g., monkey) it has two main lobes—a larger superficial and a smaller deeper lobe between which lies the facial nerve (Gregoire). Other oral glands (e. g., orbital, zygomatic) appear in some mammals.

THE TEETH

The **teeth** [dentes] are highly specialized structures developed in the oral mucosa as organs of mastication and also (in man) of speech. The adult individual with perfect dentition has thirty-two teeth, arranged arch-like in the sock-

FIG. 892.—TEETH OF ADULT, LINGUAL SURFACES. (Broomell and Fischelis.)

FIG. 893.—TEETH OF ADULT, LABIAL AND BUCCAL SURFACES. (Broomell and Fischelis.)



ets (alveoli) of the maxilla and the mandible. Sixteen belong to the upper or maxillary arch; and sixteen to the lower or mandibular. The four central teeth in each dental arch are the *incisors*, the tooth next to these on each side is the *canine* (cuspid); behind these are the two *premolars* (bicuspids); and lastly the three *molars*. This relation of teeth is expressed by the following dental formula:

$$i\frac{2}{2}, c\frac{1}{1}, pm\frac{2}{2}, m\frac{3}{3} = 32.$$

Forms.—Each tooth [dens] has a *crown* [corona dentis], the portion exposed beyond the gum, and covered with enamel (figs. 894, 895). The root [radix dentis] is the portion covered with cementum and embedded in the bony socket. At the line of union of crown and root is the slightly constricted *neck* [collum dentis]. The surface of the tooth directed toward the lip (or cheek) is termed the *labial* (or buccal) surface [facies labialis; f. buccalis]; while that toward the tongue is the *lingual* surface [f. lingualis]. The crowns of the opposite arches meet at the *masticating* or occlusal surface [f. masticatoria]. The surfaces in contact with the

adjacent teeth of the same arch [facies contactus] are, for the incisors and canines, termed *medial* and *lateral*, while those for the premolars and molars are termed *anterior* and *posterior*.

Structure.—As shown in longitudinal section (figs. 895, 896), each tooth has a central cavity [cavum dentis] or pulp cavity, which is filled with *pulp* [pulpa dentis]. The pulp is a soft fibrous tissue richly supplied with vessels and sensory nerves which enter the *root canal* through the apical *foramen* [foramen apicis dentis]. The body of the tooth, both crown and root, is composed of a dense modified variety of bone called *dentine* [substantia eburnea]. It is yellowish in color. The striated appearance of the dentine is due to numerous fine canals, the *dentinal tubules* [canaliculi dentales]. These contain 'Tomes' fibrils,' which are long protoplasmic branches of the *odontoblasts*, a layer of cells on the surface of the pulp. At the outer surface of the dentine in the root are numerous small, irregular *interglobular spaces*, corresponding to Tomes' 'granular sheath' (fig. 896). The dentine of the crown is covered with a layer of white *enamel* [substantia adamantina], which is the hardest substance in the body. It is composed of numerous minute hexagonal *prisms* [prismata adamantina] which are arranged perpendicular to the surface and are of epithelial origin. In adult teeth, the enamel is often worn through in places, exposing the yellowish dentine. The dentine of the root is covered by a thin layer of

FIG. 894.—CANINE TOOTH, LINGUAL SURFACE.

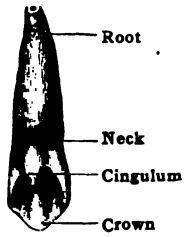


FIG. 895.—A MOLAR TOOTH IN SECTION

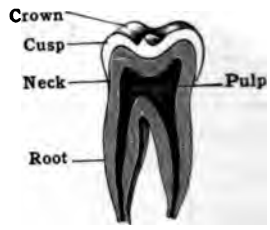


cementum [substantia ossea], a layer of modified bone which is very thin at the neck, but becomes thicker toward the root apex (fig. 896). Surrounding the root is the *alveolar periosteum* [peridental membrane), a fibrous membrane connecting the cementum firmly with the bony lining of the socket. For further details of the minute structure of teeth, works on histology may be consulted.

The relations of the teeth and alveoli are well shown by the X-rays (fig. 898).

Gums.—Covering the alveolar portions of the maxilla and mandible are the gums [gingivæ]. They are continuous with the mucosa of the oral vestibule externally and of the palate or floor of the mouth internally. Like the mucosa of the mouth elsewhere, they are covered with stratified squamous epithelium. The lamina propria is especially thick and strong, and is firmly attached to the subjacent bone. Around the neck of each tooth, the epithelium of the gum forms an overlapping collar and the lamina propria is continuous with the alveolar periosteum (peridental membrane) (fig. 896).

The incisors.—(Figs. 892, 893, 897.) The incisor teeth [dentes incisivi] are so named on account of their function in cutting the food. The *crown* has a characteristic chisel-shape. The *masticating* surface is narrow and chisel-edged. In recently erupted teeth, the cutting edge is elevated into three small cusps, which soon wear down, leaving a straight edge. These cusps correspond to three indistinct ridges on the labial surfaces. The lateral angle of the crown is usually more rounded than the medial. The *labial* surfaces are slightly convex, the *lingual* slightly concave. The *contact* surfaces are somewhat triangular. The *roots* of the incisors are single, though often longitudinally grooved, indicating traces of a division. They are somewhat conical, but flattened from side to side, especially the lower set, and are slightly curved lateralward.

The upper or maxillary incisors are much larger than the lower. They are lodged in the premaxilla, and are inclined downward and forward. They overlap the lower incisors in mastication, hence the masticating surface is worn off and rounded at its posterior edge, while the anterior edge becomes sharp and chisel-like. The lingual surfaces of the crowns terminate near the gum in a low, inverted V-shaped ridge, the basal ridge or *cingulum*. At the apex of the V, near the gum, there is often (especially on the lateral incisor) a small *lingual cusp*. The medial upper incisor is distinguished from the lateral by its such larger size.

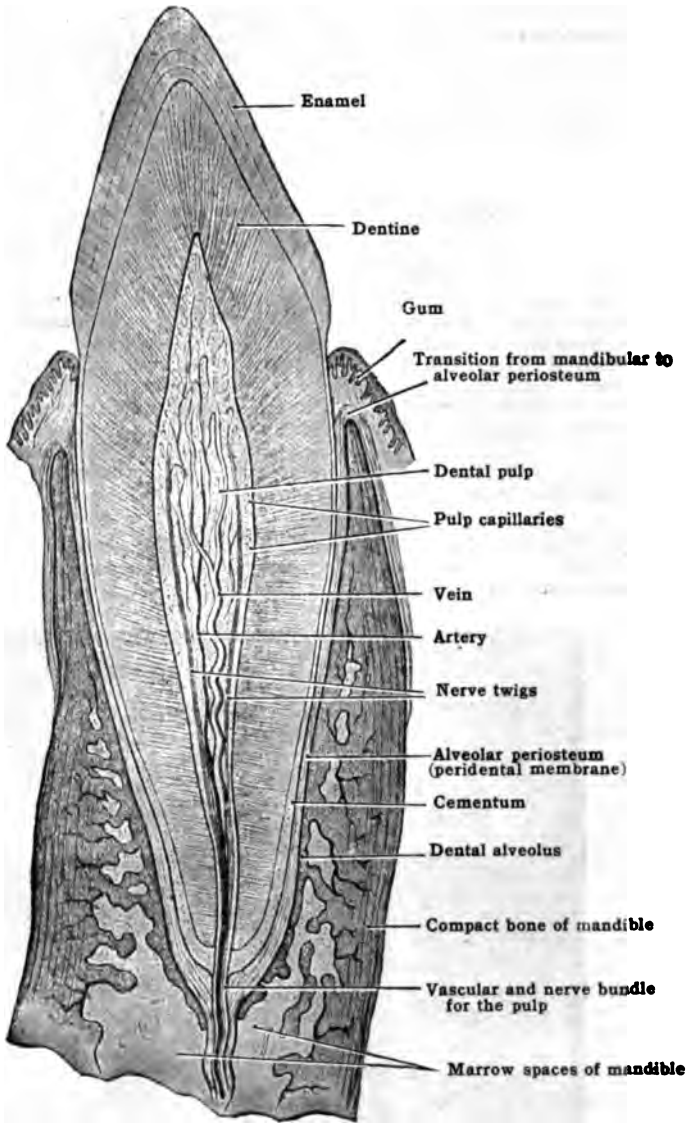
The lower or mandibular incisors are smaller than the upper, the cutting edges being only about half as wide. Being overlapped by the upper set, the lower incisors have the masticating surface worn off anteriorly, leaving a sharp cutting edge posteriorly. The lower incisors are vertically placed, and the crown becomes narrower toward the neck. A cingulum is rarely visible. The medial lower incisor, unlike the upper, is slightly smaller than the lateral.

The canines.—(Figs. 892–894.) The canine teeth [dentes canini] so-called from their prominence in the dog-tribe, are sometimes termed the 'cuspids.' They are the longest of all the teeth. The *crown* is thicker and more conical than in the incisors. The *masticating* surface forms a median angular point, on either side of which the cutting edge slopes to the lateral

[redacted]le. The medial limb of the cutting edge is usually somewhat shorter than the lateral, ren[redacted]g the crown asymmetrical. The *labial* surface is convex, the *lingual* somewhat concave. [redacted] *root* is single, long, flattened from side to side and grooved on the sides as in the incisors. [redacted] canine root is usually slightly curved lateralward. The bony alveolar protuberances [juga [redacted]olaria] are more prominent than those of any other teeth.

The **upper canine** slants forward and overlaps the lower, as in the incisors. The upper [redacted]ne also presents a well-marked *cingulum*, and usually a distinct *lingual cusp* (fig. 894) [redacted]ow which a slight median ridge extends along the lingual surface. On the **lower canine,**

FIG. 896.—VERTICAL SECTION OF AN INFERIOR CANINE TOOTH, IN SITU. × 4. (From Toldt's Atlas.)



these structures are poorly marked or absent. The lower canine is somewhat smaller than the upper, and its root is occasionally bifid.

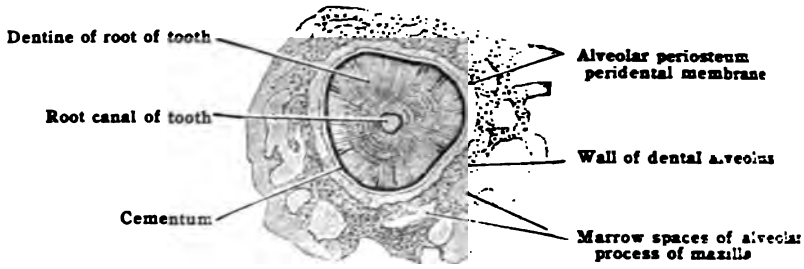
The premolars.—(Figs. 892, 893, 899, 900.) The premolars [dentes premolares] are so named on account of their position in front of the molars. The *crown* presents on the masticating surface two prominent cusps, on account of which the premolars are often called 'bicuspids.' The *buccal* and *lingual* surfaces are convex especially from side to side, so that the crown is somewhat cylindrical in form, with flattened, quadrilateral anterior and posterior *contact* surfaces. The *root* is (usually) single and more or less flattened anteroposteriorly, and usually somewhat curved backward.

The **upper premolars** are distinguished from the lower by a greater anteroposterior flattening of the crown and by a deep groove separating the cusps (excepting at their anterior and posterior margins) on the masticating surface. In the *first* upper premolar the lingual cusp

and surface are decidedly smaller than the buccal; and the root is frequently bifid or a (occasionally even triple). In the *second* upper premolar the lingual cusp and surface a large as the buccal; and the root, though deeply grooved, is rarely bifid.

In the **lower premolars,** the crowns are more cylindrical in form, and the cusps are u by a median ridge so that the masticating surface presents two small pits. The roots are rounded and tapering, and rarely grooved. In the *first* lower premolar (like the corresp upper) the lingual cusp and surface are much smaller than the buccal, the lingual cusp s times being rudimentary; while in the *second* they are more nearly equal. The second

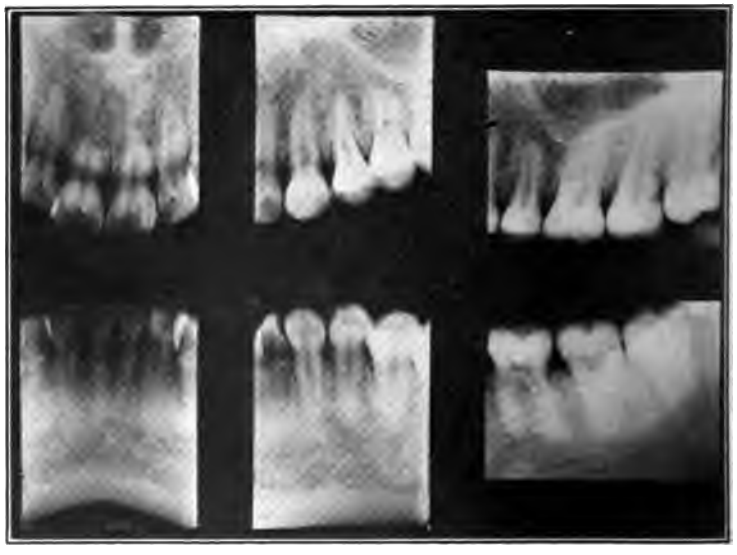
FIG. 897.—CROSS-SECTION OF THE MEDIAL UPPER INCISOR, IN SITU. × 4. (From T Atlas.)



premolar is often slightly larger than the first, while in the upper premolar the convers It should be noted, however, that the premolars are quite variable in all respects, s therefore often difficult to identify the individual isolated teeth.

The molars.—(Figs. 892, 893, 895, 899.) The molars (dentes molares) or 'grind characterized by their large size, and by the presence of three to five masticating cusp sometimes called 'multicuspids'). The *crowns* are massive, somewhat resembling cubes, and the lingual and buccal surfaces present vertical grooves continuous with the separating the cusps. The *pulp-cavity* (fig. 895) has slight extensions corresponding cusps, and also communicates with the canals of the *roots*, which are usually two or number, and more or less curved.

FIG. 898.—RADIOGRAPH OF THE TEETH. (DR. R. D. Carman, Mayo Clinic.) Up lower teeth of one side shown; incisors on the left, canine and premolars in the molars to the right.



The **upper molars** are most easily distinguished from the lower by the presence of root. The masticating surface is nearly square with rounded angles. They each have t four cusps, separated by grooves resembling a diagonally placed H (fig. 880). The cr the upper molars are obliquely placed so as to slant downward and slightly latera

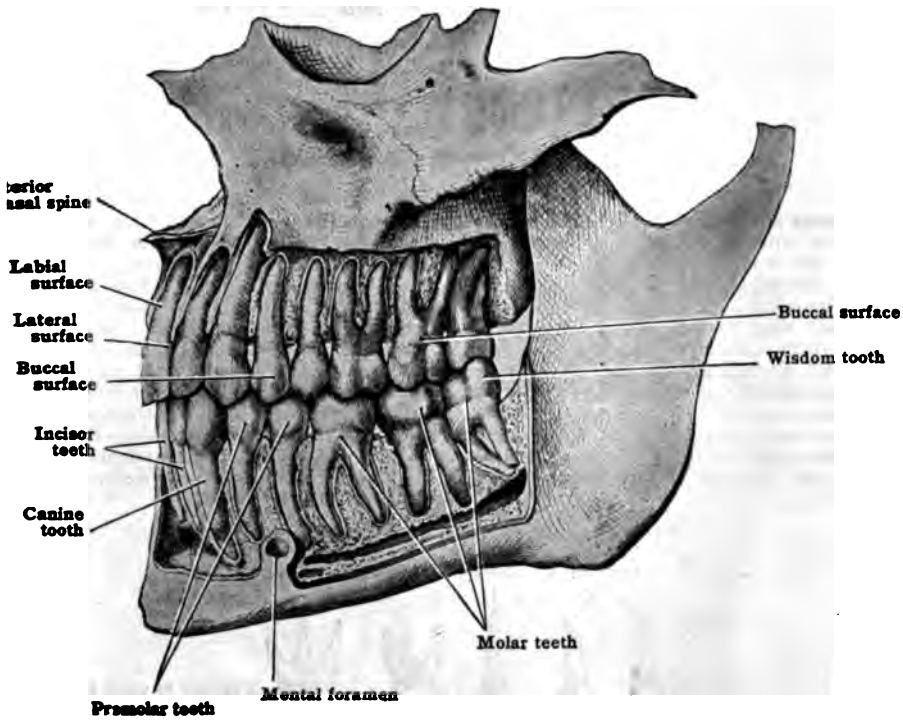
Each upper molar has three roots, two buccal and one lingual or palatal. They (especially the buccal) in more or less close relation with the floor of the maxillary ant Highmore) (fig. 899). The buccal roots are flattened anteroposteriorly, and longit grooved, and bent backward. The palatal root is more rounded, with a groove on th surface, and usually bent medialward. Either of the buccal roots may fuse with the or there may be an extra fourth root.

As to the *individual* upper molars, the *first* has almost invariably four typical cusps (rarely r three, or with an additional fifth rudimentary). The *second* upper molar has only three ps in about half of the cases (in Europeans), and four in the remainder. The *third*, or wisdom th [dens serotinus] is exceedingly variable in size and form. It has three cusps much more uently than four, and its three roots are often more or less fused into a conical mass. It sually much smaller than the other molars, and is absent in nearly one-fifth of all cases.

The lower molars have usually four or five cusps (two lingual, and two or three buccal) fissures separating them being cross-shaped or stellate (fig. 889). The crowns incline upd and slightly medialward. They have each two roots, anterior and posterior, flattened eroposteriorly, and usually somewhat curved backward. The roots, especially the anterior, y be longitudinally grooved. The anterior has two root-canals, the posterior usually only one. e apices of the roots of the lower molars, especially of the third, approach the mandibular ferior dental) canal (fig. 899).

Of the *individual* lower molars, the *first* is usually slightly the largest, and has five cusps the great majority of cases (variously estimated at from 60 to 95 per cent.), otherwise four. ie four main cusps (two buccal and two lingual) are separated by a cruciform fissure, which furcates posteriorly to embrace the small fifth cusp (which is placed slightly to the buccal

FIG. 899.—DISSECTION SHOWING THE ROOTS OF THE TEETH. Teeth in Occlusion. ×1. (From Toldt's Atlas.)



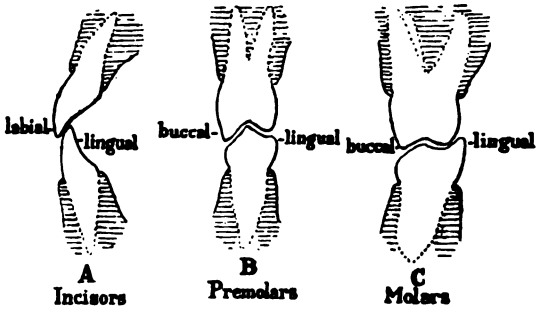
le) when present. The *second* lower molar has usually four cusps (75 to 85 per cent. of cases), nerwise five, the fifth usually small or rudimentary. The roots are sometimes confluent. ie lower *third* or wisdom tooth [dens serotinus], like the upper, is usually small and exceedgly variable. It has usually four or five cusps; but the number may be increased to six or ven, or reduced to three, two, or one. The roots are often short and fused into a conical ass, in which sometimes only a single canal is present.

The dental arches.—On comparing the upper and the lower dental arches, it is seen that e upper (fig. 880) forms an elliptical curve, while the lower (fig. 889) resembles a parabola. ie upper arch is slightly larger (due chiefly to the slant of the teeth, as previously explained) that it slightly overlaps the lower when the teeth are in occlusion. Thus, as shown in fig. 9, the upper incisors (and canines) overlap the lower. The buccal cusps of the lower preolars and molars fit into the groove between the upper buccal and lingual cusps; while the per lingual cusps correspond to the groove between lower buccal and lingual cusps. This rangement favors a more perfect mastication (see fig. 900).

Moreover, when viewed from the side (fig. 899), it is seen that in general, the corresponding eth of the upper and the lower arches are not opposite, but alternate with each other. This due chiefly to the great width of the upper central incisor. The lower molars, however, espeally the third, are wider (anteroposteriorly) than the upper, so that the two arches are arly equal in length. The interdental line between the two arches is not straight, but slightly nvex downward (fig. 899). In both arches, the crowns of the incisors and canines are taller an those of the premolars and molars.

Vessels and nerves.—The vessels and nerves of the teeth are distributed partly to the pulp and partly to the surrounding alveolar periosteum. The *arteries* are all derived from the internal maxillary. Those for the upper teeth are the posterior superior alveolar and the anterior superior alveolar (from the infraorbital). Similar branches to the lower jaw are given off by the inferior alveolar. They give off twigs to the gums (rami gingivales), the alveolar periosteum (rr. alveolares), and the pulp cavities (rr. dentales). A dental branch enters each root canal through the apical foramen, and breaks up into a rich peripheral capillary plexus under the odontoblast layer. From this plexus, the corresponding *veins* arise. There is a plexus of peridental *lymphatics*, which anastomose with those of the surrounding gums, and drain chiefly into the submaxillary nodes. Lymphatics have also been demonstrated in the pulp of the tooth (Schweitzer).

FIG. 900.—DIAGRAM SHOWING THE ARTICULATION OF THE TEETH. (Poirier-Charpy.)

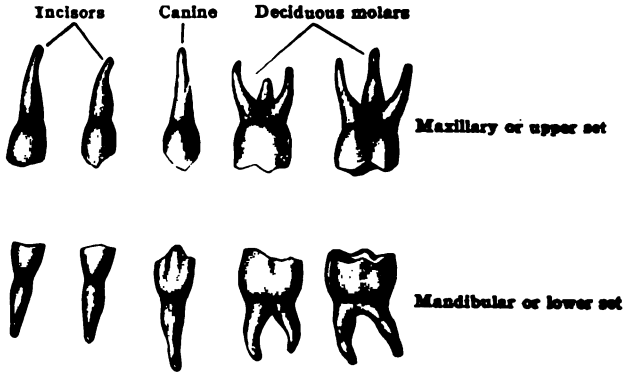


The **nerves** are sensory branches derived from the trigeminus. Those for the upper teeth are from the anterior, middle, and posterior superior alveolar (fig. 765); while those for the lower teeth are from the inferior alveolar (fig. 766). These nerves give numerous branches to the gums, alveolar periosteum (peridental membrane), and pulp cavities. The latter enter with the corresponding vessels, and their distribution within the tooth is a subject of controversy. They may be followed easily to a plexus under the odontoblasts; but whether they end freely, or in connection with the odontoblasts (which by some are considered as peripheral sensory cells), or send fine terminal branches out into the dentinal canals is still uncertain.

Development of the teeth.—The teeth represent calcified papillæ of the oral mucosa, the enamel being a derivative of the ectodermal epithelium, and the remainder of the tooth coming from the underlying mesenchyme. The early development of the teeth is described on p. 38.

Surrounding the entire developing tooth there is formed a strong, fibrous connective tissue membrane, the *tooth-sac*. The deeper part of this sac later becomes the *alveolar periosteum*

FIG. 901.—THE DECIDUOUS TEETH, EXTERNAL VIEW.



(peridental membrane) around which the bony alveoli are formed. This bone may entirely surround the tooth-sac, excepting at the summit, where a foramen persists through which a process of connective tissue (*gubernaculum dentis*) connects the tooth-sac with the overlying gum (see fig. 177.) Upon the inner surface of the tooth-sac, next to the root, the bony *cementum* is deposited upon the dentine. The root gradualy elongates, and is usually not completed until long after the eruption. The remaining superficial portion of the tooth-sac undergoes pressure atrophy and absorption. The remnants of the enamel organ, however, persist and form a thin tough cuticle [cuticula dentis], *Nasmyth's membrane*, which is soon worn off when the crown is exposed at the surface.

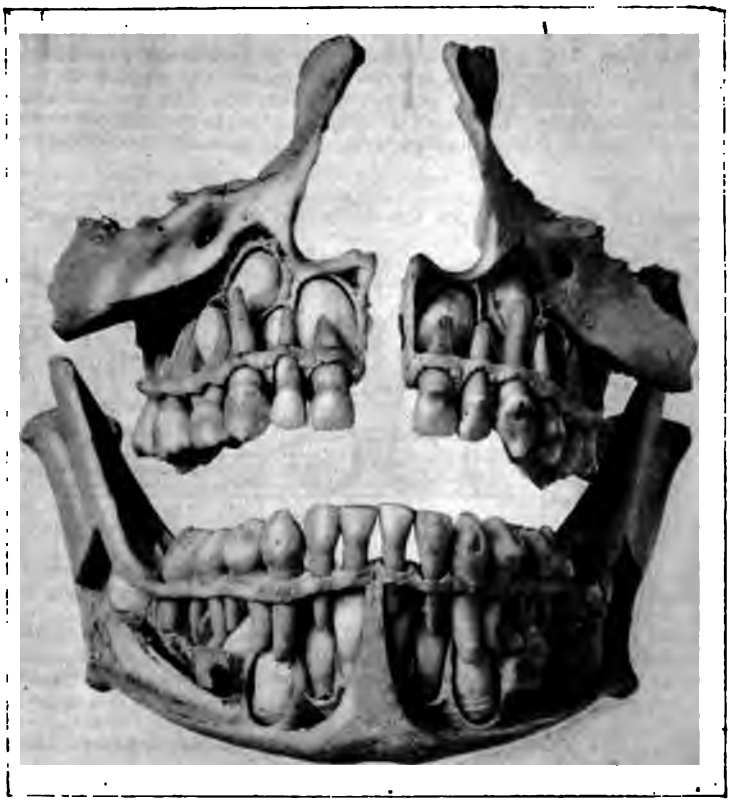
From the remainder of the dental ridge, which lies on the lingual side of the deciduous teeth (fig. 39), the *permanent teeth* are later derived in a very similar manner. (Rudimentary

indications of a *prelacteal* dental ridge have also been described.) The anlages of the permanent teeth therefore lie to the lingual side of the deciduous (fig. 902). From the posterior end of the dental ridge a process extends into the jaw behind the deciduous teeth, and from this process the permanent molars (which have no deciduous predecessors) are formed. At birth, although no teeth have yet been cut, there are present in the gums the anlages of not only all of the deciduous teeth, but also all of the permanent teeth, with two exceptions. Those of the second molars do not appear until six weeks after birth, and of the third molars not until the fifth year. The remnants of the dental ridges become broken up into small masses of epithelial cells, which persist for a variable time, forming the so-called 'glands' of Serres or Black.

The deciduous teeth.—The deciduous [dentes decidui], temporary or milk teeth are twenty in number, corresponding to the following formula:

$$\text{di}\,\frac{2}{2},\ \text{dc}\,\frac{1}{1},\ \text{dm}\,\frac{2}{2} = 20.$$

FIG. 902.—DISSECTION SHOWING BOTH DECIDUOUS AND PERMANENT TEETH AT ABOUT SIX YEARS. (Broomell and Fischelis.)



The deciduous teeth (figs. 901, 902) are much smaller in size than the permanent teeth, and their necks are more constricted. The enamel of the crown-cap is thicker. In general, their form and structure otherwise are very similar to that already described in the case of the permanent incisors and canines. The molars, however, are different. Their cusps on the masticating surface are very sharp and irregular. There are usually three cusps on the first upper molar and four on the second; four cusps on the first lower molar and five on the second. The roots correspond to those of the permanent molars (three above and two below), but they are much more divergent, to allow room for the development of the corresponding subjacent permanent premolar teeth. The first molar is always considerably smaller than the second.

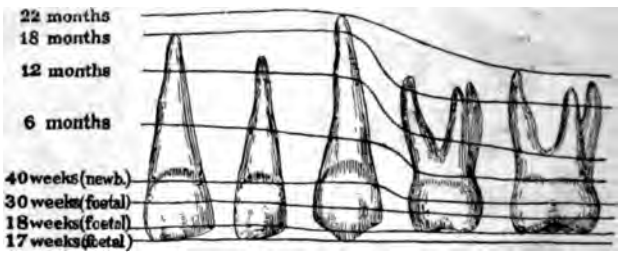
Calcification in the dentine and enamel of the teeth does not begin until the anlages of the crowns are well formed. The process of calcification follows that of the development of the tooth in general, beginning in the superficial portion of the crown and gradually spreading toward the root. Calcification in the *deciduous* teeth begins during the fifth fetal month, and at birth the crowns are nearly completed (fig. 904). Of the *permanent* set of teeth, only the first molar has begun to calcify at birth (fig. 905). Calcification of the other permanent teeth begins as follows: incisors, first year; canines, third year; premolars, fourth and fifth years; second molars, fifth year; third molars, eighth or ninth years. There are, however, great

variations in the time at which the calcification of the various teeth begins. As a rule, th calcification of the roots is not completed at the apices until some time after the crowns a exposed in eruption. As shown by fig. 905, calcification in most of the teeth is comple between the tenth and twelfth years; but in the second molars not until the sixteenth ye and in the third molars at eighteen years or later.

FIG. 903.—GROWTH OF THE ROOT AND PULP-CAVITY OF THE UPPER FIRST MOLAR, FROM TH FIFTH TO THE NINTH YEAR. (Broomell and Fischelis.)

Eruption of the teeth.—On account of pressure due to growth and expansion at the root the tooth (and probably other obscure factors), the crowns are pushed toward the surfa The overlying portion of the tooth-sac, together with corresponding portions of the tempor alveolar bone, are absorbed, and the crown is 'cut,' i. e., breaks through the surface of the g in eruption. In the case of the permanent teeth, this is normally preceded by a sheddin

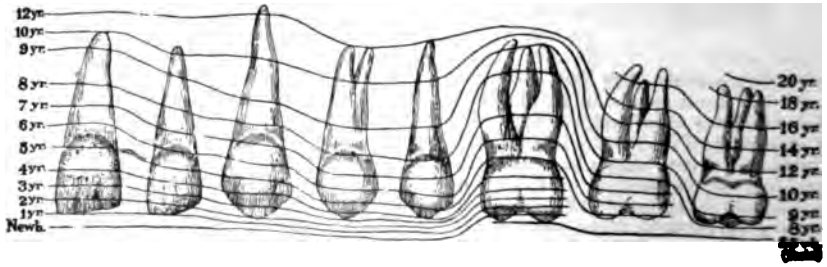
FIG. 904.—SHOWING THE EXTENT OF CALCIFICATION OF DECIDUOUS TEETH. (Peirce.



the deciduous teeth. The latter have been loosened by the absorption of their roots, whic perhaps due largely to the activity of certain *odontoclasts* (like the osteoclasts of bone) wh are found in the region of absorption.

Time and order of eruption.—The *time* of the eruption of the various teeth is subject great variation, so that no two investigators agree upon it. Aside from the wisdom teeth, time of eruption is most variable in the canines and premolars, and least variable in the f

FIG. 905.—SHOWING THE EXTENT OF CALCIFICATION OF THE PERMANENT TEETH. (Peir



permanent molars (Röse). According to Röse, the eruption averages four and one-half mon earlier in the male, and is also earlier in well-to-do and city children. But Boas and Bean f the eruption usually earlier in girls than in boys. The *order* in which the teeth appear is l variable. The average time at which the various deciduous and permanent teeth appear a are shed is indicated approximately in the following table. The lower teeth usually er before the corresponding upper teeth.

A. Deciduous Teeth

	Eruption Occurs	Shedding Begins
Medial incisors	7 (6–8) months	7th year
Lateral incisors	9 (7–12) months	8th year
First molars	14–15 months	10th year
Canine	18–19 months	10th year
Second molars	20–24 months	11th–12th year

B. Permanent Teeth

The approximate age (in years) at which the eruption of each of the permanent teeth has occurred in 50 per cent. of the individuals examined, which corresponds to the time of most rapid eruption, is given in the following table (observations of Bean upon 1445 school children at Ann Arbor, Michigan, and of James and Pitts on 4850 English children). The lower teeth, excepting the premolars, usually appear before the corresponding upper teeth.

	American		English
	Girls	Boys	
First molars	6.0	6.5	5.75– 6.25
Medial incisors	6.5	7.0	6.25– 7.50
Lateral incisors	8.0	8.5	7.50– 8.75
First premolars	10.0	11.0	9.75–10.50
Canines	10.5	11.5	10.25–11.75
Second premolars	10.0	11.5	10.75–12.00
Second molars	11.5	12.5	11.75–(12+)

The third molars (wisdom teeth) are extremely variable, usually erupting between the ages of 17 and 25, but sometimes later and occasionally failing to appear at all.

Variations.—The great variability of the teeth has already been emphasized, and numerous variations described in connection with the various individual teeth and their development. The observations of James and Pitts show a range of 4 or 5 years in the date at which eruption occurs. Bean has shown that there is marked racial variation in this respect. In *number*, the teeth may be reduced, due to absence (oftenest of the third molar) or incomplete development with failure of eruption. An *increase* in the normal number is less common. It may be only apparent, due to the retention of a deciduous tooth. There may rarely, however, be a true extra third incisor or premolar, or a fourth molar. Aberrant teeth may occur either on the labial or palatal side of the dental arch. A third dentition appears rarely in old age. In *form*, there is much greater variation as before mentioned. All intermediate forms between rudimentary and fully developed teeth may occur. Fusion between neighboring teeth is sometimes found, and deformities in the dental arches necessarily accompany palatal defects involving the alveolar arches.

Comparative.—As the oral mucosa represents an invagination of the integument, so the teeth are morphologically equivalent to modified dermal papillæ. The close relationship between the teeth and the dermal appendages is clearly shown among many of the lower vertebrates, but most clearly in the Selachians (which include sharks and allied forms). In fig. 906, which illustrates a sagittal section through the lower jaw of a young dogfish, it is clearly evident that the external placoid scales or 'dermal teeth' are continuous with the equivalent oral teeth at the oral margin of the jaw. Both the dermal teeth and the oral teeth are composed of dentine which presents an enlarged base and a somewhat conical apex. The base is embedded in the fibrous lamina propria (often in bony plates) while the apex projects through the epithelium and is covered with a thin cuticular layer the 'enamel membrane.' True enamel is usually rudimentary or absent in the primitive teeth of lower vertebrates, and represents a secondary acquisition. The dentine is in all cases derived from the connective tissue, and the enamel from the epithelium.

The process of development of the primitive oral teeth is also illustrated in fig. 906. Just within the oral margin there is a shelf-like downgrowth of the ectodermal epithelium, forming a primitive germinal ridge. Along this ridge may be seen the anlages of several rows of teeth in various stages of development. As fast as the mature teeth at the oral margin are worn off, new teeth pass up from below to replace them. Thus the primitive form of dentition is *polyphyodont*, with many sets of teeth developed successively throughout life. As we pass up the vertebrate scale there is a tendency to a reduction in the number of sets, although there is a wide variation among the various forms. In most mammals, as in man, the number of sets of teeth has been reduced to two, or *diphyodont* dentition, with only traces of an earlier (prelacteal) and also a later (post-permanent) set. In some mammals (nomotremes, cetacea) the dentition has been reduced to a single set, *monophyodont*, while in birds all except rudimentary traces of dentition have been lost.

As may be further observed in fig. 906, the primitive teeth are of a recurved conical form, and serve primarily for grasping and holding the food. The specialization of the teeth for purposes of mastication is in general a secondary acquisition amongst higher vertebrates.

It is also noteworthy that the primitive teeth, as found among nearly all forms below the mammals, are practically alike in form, i. e., *homodont*. Among mammals, however, there is a marked specialization of the teeth, or *heterodont* dentition. The mammalian teeth are usually differentiated into four distinct classes, incisors, canines, premolars and molars, similar to those found in man.

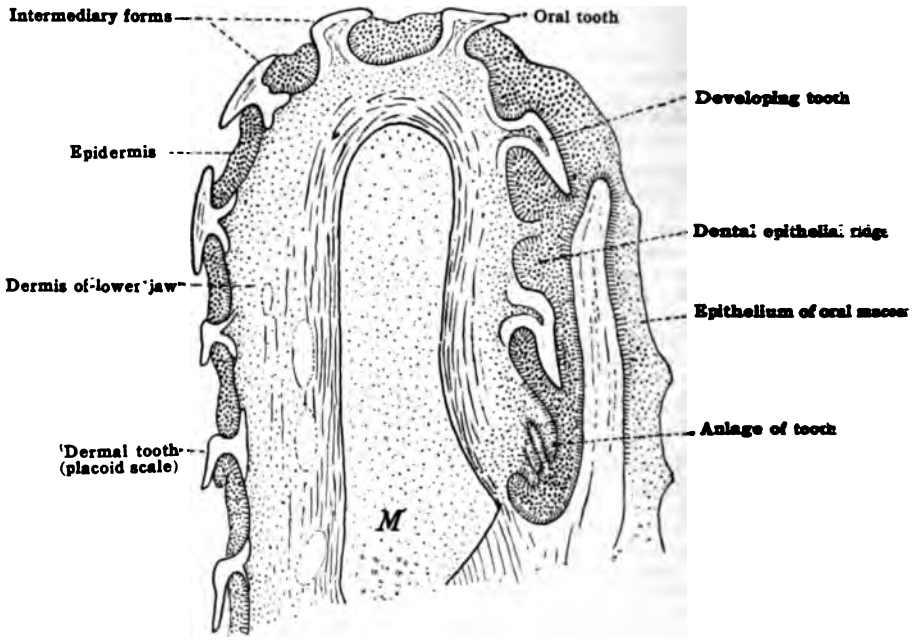
The typical or complete mammalian dentition (found in mole, pig and young horse), however, contains a larger number of teeth than found in man, and is represented by the formula:

$$i\ \frac{3}{3},\ c\ \frac{1}{1},\ pm\ \frac{4}{4},\ m\ \frac{3}{3} = 44.$$

Thus it is evident that there has been a reduction in the incisors and premolars in the human species, and there has been considerable discussion of the question as to which teeth of the primitive series have been lost. This reduction in the number of teeth is probably correlated with the general reduction in the jaws, which are relatively much larger and stronger in the savage races and lower animals. The third molar, or wisdom tooth, is probably now on the road to extinction, due to a continuation of the same evolutionary process.

Another interesting problem, concerning which there has been much speculation, is the origin of the multicuspidate mammalian molar. It has clearly been derived from the primitive conical type of the homodont dentition, but as to the method of evolution there is a difference of opinion. According to one view (the 'concrescence' theory), the molar has been derived by a process of fusion, each cusp representing a primitive conical tooth. Another view (the

FIG. 906.—SECTION THROUGH LOWER JAW OF DOG-FISH, SHOWING THE DEVELOPMENT OF THE ORAL TEETH, AND THE TRANSITION TO DERMAL TEETH. M, mandible. (After Gegenbaur.)



'differentiation' theory) is that the molar represents a single primitive tooth, upon the crown of which the various cusps have been differentiated. According to a third view, which is a compromise, the tritubercular (tricuspid) form of tooth, which is that found in the earliest fossil mammals, was derived by a process of concrescence of three primitive teeth, while from this tricuspid form the multicuspidate molar has been derived by a process of differentiation.

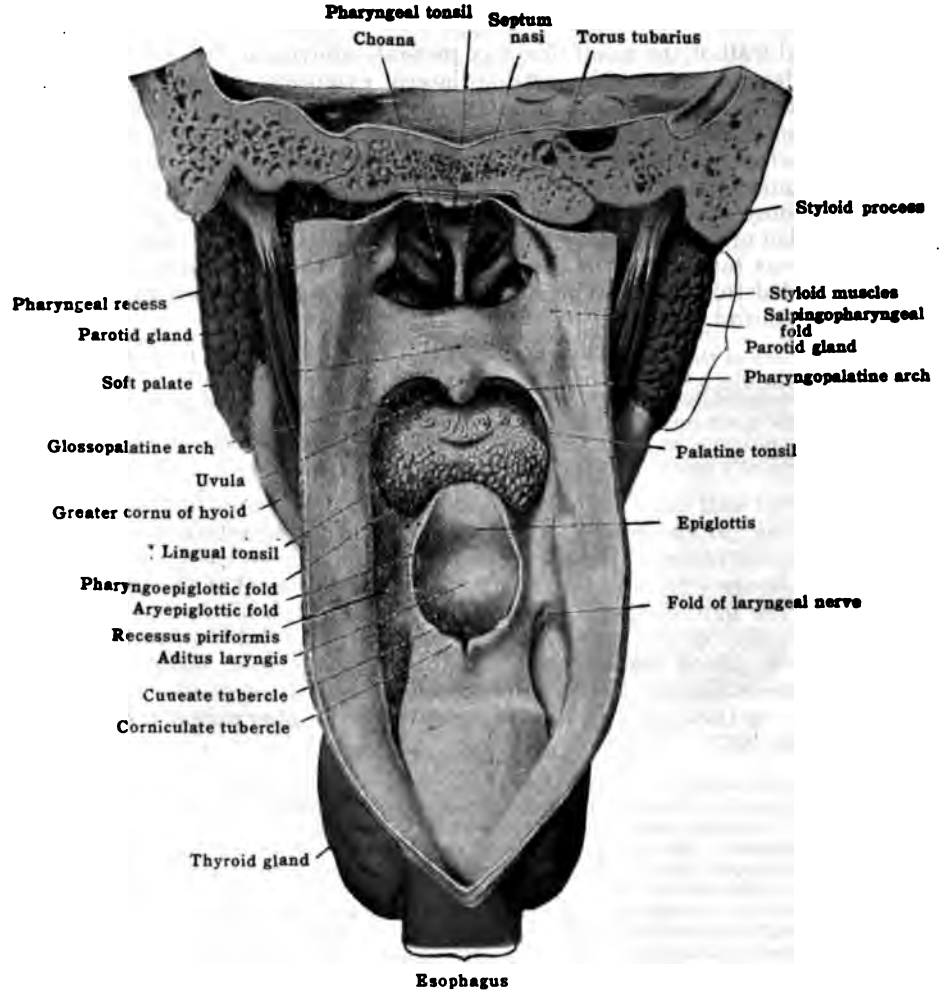
THE PHARYNX

The **pharynx** is a vertical, tubular passage, flattened anteroposteriorly, and extending from the base of the cranium *above* to the beginning of the esophagus below. *Posteriorly*, it is in contact with the bodies of the upper six cervical vertebræ. *Laterally*, it is in relation with the internal and common carotid arteries, the internal jugular vein, the sympathetic and the last four cranial nerves. *Anteriorly*, it communicates above with the nasal cavity, beneath this with the oral cavity, and below with the laryngeal cavity. The pharynx is correspondingly divided into three parts: the *nasal pharynx* [pars nasalis], which is exclusively respiratory in function; the *oral pharynx* [pars oralis], which is both respiratory and alimentary; and the *laryngeal pharynx* [pars laryngea], which is almost entirely alimentary.

Size and form.—The average length of the pharynx is about 12 cm. (5 inches). It is widest at the nasal pharynx, with a constriction (isthmus) at the junction

with the widened oral pharynx, and is again somewhat narrowed at the junction of oral and laryngeal pharynx (fig. 907). It is narrowest at the point where it joins the esophagus below. In sagittal section (fig. 876), it is evident that the anterior and posterior walls are closely approximated in the laryngeal pharynx, and have only a small space between them in the oral pharynx. The nasal pharynx, however, has a considerable anteroposterior depth, and by its bony walls is always kept open for respiratory purposes.

FIG. 907.—THE INTERIOR OF THE PHARYNX, VIEWED FROM BEHIND. (Sobotta-McMurrich.)



Structure.—The pharynx approaches the typical structure of the alimentary canal, yet differs from it in several important respects. The lining *mucosa* is continuous with that of the various cavities which open into the pharynx. Above, it is closely adherent to the base of the cranium, where it is thick and dark in color. It becomes thinner where it approaches the openings of the auditory tubes and choanæ; and below it is paler and thrown into longitudinal folds.

External to the mucosa, there is a characteristic fibrous membrane, the *pharyngeal aponeurosis* [fascia pharyngobasilaris], which is well marked above, but below it loses its density and gradually disappears as a definite structure. Above, it is attached to the basilar portion of the occipital bone in front of the pharyngeal tubercle. Its attachment may be traced to the apex of the petrous portion of the temporal bone, and thence to the auditory (Eustachian) tube and medial lamina of the pterygoid process. It descends along the pterygomandibular ligament to the posterior end of the mylohyoid ridge of the lower jaw, and passes thence along the side of the tongue to the stylohyoid ligament, the hyoid bone, and thyroid cartilage.

External to the pharyngeal aponeurosis is a thick *muscular* layer, made up of various cross-striated muscles, as will be described later. Outside of the muscular layer is a thin fibrous tunica adventitia, connected with the adjacent prevertebral fascia by a loose, areolar tissue. This loose tissue allows movement of the pharynx, and also favors the spreading of post-pharyngeal abscesses.

The **nasal pharynx** (figs. 876, 907) belongs, strictly speaking, with the nasal fossa as a part of the respiratory rather than the digestive system. . **Its anterior wall** is occupied by the two *choanæ* (posterior nares), with the nasal septum between them. The *floor* is formed by the upper surface of the soft palate and is a direct posterior continuation of the floor of the nasal fossæ. Posteriorly, however, the floor presents a more or less narrowed opening, the *pharyngeal isthmus*, which communicates with the oral pharynx below.

The isthmus is formed anteriorly by the uvula, laterally by the posterior (pharyngopalatine) arches. These slope backward and downward to the posterior wall of the pharynx, which forms the posterior boundary of the isthmus. The floor and isthmus change their form and position greatly during the action of the palatal muscles, as will be mentioned later.

The **lateral wall** of the nasal pharynx presents above and behind, corresponding to its widest point, a wide, slit-like lateral extension, the *pharyngeal recess* [recessus pharyngeus] or fossa of Rosenmueller (fig. 907). Below and in front of this recess, the greater part of the lateral wall is occupied by the aperture of the auditory (Eustachian) tube [ostium pharyngeum tubæ]. This is a somewhat triangular, funnel-shaped opening, with an inconspicuous *anterior lip* [labium anterius], a more distinct *posterior lip* [labium posterius], which presents posteriorly a rounded prominence (due to the projecting cartilage of the auditory tube), called the *torus tubarius*. On the lower aspect of the triangular aperture is a slightly rounded fold, the *levator cushion*, which is a prominence caused by the levator veli palatini muscle.

The prominence of the posterior lip facilitates the introduction of the Eustachian catheter, in connection with which the location of the aperture in the midlateral wall just above the level of the floor of the nasal fossa should be carefully noted. A fold of mucosa descending from the posterior lip of the aperture to the lateral pharyngeal wall is the *plica salpingopharyngea* (due to the m. salpingopharyngeus). An inconspicuous *plica salpingopalatina* descends from the anterior lip to the soft palate.

The **posterior wall** (fig. 876) of the nasal pharynx slopes from below upward and forward, passing (at the level of the anterior arch of the atlas) into the *roof* or *fornix* [fornix pharyngis]. The fornix is attached chiefly to the basioccipital and basisphenoid bones, extending laterally to the carotid canal of the pyramid, and anteriorly to the base of the nasal septum. The mucosa of the fornix and to a certain extent also of the posterior wall, especially in children, is thrown into numerous folds, which contain much lymphoid tissue, both diffuse and in the form of numerous characteristic lymphoid nodules, with crypt-like invaginations of the surface epithelium. This area constitutes the **pharyngeal tonsil** [tonsilla pharyngea] (fig. 907).

The pharyngeal tonsil is well developed in children (often abnormally enlarged, producing 'adenoids'), but usually, though not always, atrophied in the adult. According to Symington, the involution of the pharyngeal tonsil begins at 6 or 7 years, and is usually completed at 10 years. In the region of the pharyngeal tonsil and elsewhere, the mucosa presents numerous small racemose mucous glands, especially thick in the palatal floor of the nasal pharynx and similar to those of the oral cavity.

In the mucosa of this region, and closely associated with the pharyngeal tonsil, there is also found a small, inconstant blind sac, the *pharyngeal bursa*. A '*pharyngeal hypophysis*,' apparently derived from the lower end of Rathke's pouch, has also been described as constantly present (fig. 1070).

The **oral pharynx** (figs. 876, 889, 907) is continuous *above* through the pharyngeal isthmus with the nasal pharynx and *below* with the laryngeal pharynx. Its *posterior* wall presents no special features. The *anterior* wall is deficient above, where there is a communication with the mouth cavity through the *isthmus faucium*. The faucial isthmus is bounded above by the uvula, laterally by the anterior (glossopalatine) arches, and below by the dorsum of the tongue in the region of the sulcus terminalis. Below the faucial isthmus, the anterior wall of the oral pharynx is formed by the root of the tongue, which has been described previously. The *lateral* wall of the oral pharynx on each side presents the *palatine tonsil*, enclosed in a somewhat triangular *tonsillar fossa* [sinus tonsillaris] limited anteriorly and posteriorly by the anterior and posterior palatine arches, and below by the root of the tongue.

The **palatine arches** (pillars) are folds of the mucosa formed at the sides of the free posterior border of the soft palate, as already mentioned in connection with that organ. The *anterior arch* [arcus glossopalatinus] extends from the soft

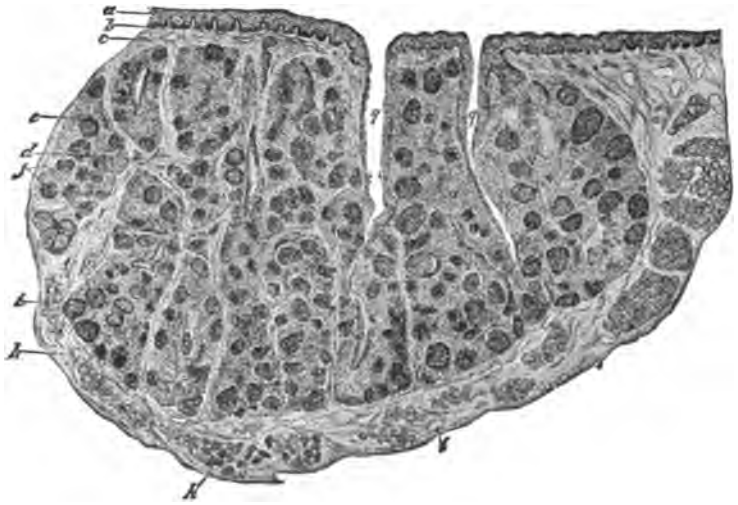
palate downward and forward to the lateral margin of the tongue, just behind the papillæ foliatæ. It is a fold of mucosa due to the underlying glossopalatine muscle, and inconspicuous except when this muscle is in action, or when the tongue is depressed. It forms the lateral boundary of the faucial isthmus. The *posterior arch* [arcus pharyngopalatinus] is a more prominent fold which extends from the soft palate in the region of the uvula downward and backward to join the posterolateral aspect of the pharyngeal wall. It forms the lateral boundary of the pharyngeal isthmus, and encloses the pharyngopalatine muscle, whose action will be explained later.

The Palatine Tonsil

The **palatine tonsil** [tonsilla palatina] (figs. 889, 908, 909) is a flattened ovoidal body, usually visible through the mouth cavity and faucial isthmus, and located on each side of the oral pharynx. The tonsil is extremely variable in size, but in the young adult averages 20 to 25 mm. in height, 15 to 20 mm. in width (anteroposteriorly) and about 12 mm. in thickness. The weight averages 1.4 grams (Gundobin).

The **lateral** or attached **surface** of the tonsil is covered by a thin but firm fibrous *capsule*, which is continuous with the pharyngeal aponeurosis, and in contact with the superior constrictor muscle of the pharynx (fig. 889).

Fig. 908.—Vertical Section of a Human Palatine Tonsil. *a*, Stratified epithelium; *b*, basement membrane; *c*, tunica propria; *d*, trabeculæ; *e*, diffuse lymphoid tissue; *f*, nodules; *h*, capsule; *i*, mucous glands; *k*, striated muscle; *l*, blood vessel; *g*, crypts. (From Radasch.



Just outside the constrictor, the tonsil is in relation with the ascending pharyngeal and ascending palatine arteries, but is separated by a considerable space from the external and internal carotids. Rarely, however, the lingual or external maxillary may extend up higher than usual, so as to be in close relation with the lower aspect of the tonsil. Further lateralward, the palatine tonsil is in relation with the internal pterygoid muscle, and on the surface corresponds to a point somewhat above and in front of the angle of the mandible. The posterior border of the tonsil is thicker than the anterior, and forms a somewhat flattened surface in contact with the pharyngopalatine muscle (fig. 909).

The **medial** or free **surface** of the tonsil is covered with mucosa and presents a variable number (12 to 30) small pits which are the openings into the tubular or slit-like *crypts* [fossulæ tonsillares]. These crypts are somewhat more numerous in the upper part of the tonsil, and are sometimes branched or irregular in form. Usually they end blindly in the substance of the tonsil, surrounded by lymphoid tissue in characteristic nodular masses (fig. 908).

The lymphocytes normally migrate through the stratified squamous epithelium lining the crypts (occasionally eroding passages of considerable size), and escape into the pharyngeal and mouth cavities, where they form the so-called *salivary corpuscles*. Around the periphery of the palatine tonsil, within the capsule, are many mucous glands (fig. 908), similar to those described in connection with the lingual and pharyngeal tonsils. The ducts of the mucous glands sometimes enter the crypts, but usually pass to the surface chiefly around the margins of the palatine tonsil.

The **nasal pharynx** (figs. 876, 907) belongs, strictly speaking, with the nasal fossa as a part of the respiratory rather than the digestive system. Its **anterior wall** is occupied by the two *choanæ* (posterior nares), with the nasal septum between them. The *floor* is formed by the upper surface of the soft palate and is a direct posterior continuation of the floor of the nasal fossæ. Posteriorly, however, the floor presents a more or less narrowed opening, the *pharyngeal isthmus*, which communicates with the oral pharynx below.

The isthmus is formed anteriorly by the uvula, laterally by the posterior (pharyngopalatine) arches. These slope backward and downward to the posterior wall of the pharynx, which forms the posterior boundary of the isthmus. The floor and isthmus change their form and position greatly during the action of the palatal muscles, as will be mentioned later.

The **lateral wall** of the nasal pharynx presents above and behind, corresponding to its widest point, a wide, slit-like lateral extension, the *pharyngeal recess* [recessus pharyngeus] or fossa of Rosenmueller (fig. 907). Below and in front of this recess, the greater part of the lateral wall is occupied by the aperture of the auditory (Eustachian) tube [ostium pharyngeum tubæ]. This is a somewhat triangular, funnel-shaped opening, with an inconspicuous *anterior lip* [labium anterius], a more distinct *posterior lip* [labium posterius], which presents posteriorly a rounded prominence (due to the projecting cartilage of the auditory tube), called the *torus tubarius*. On the lower aspect of the triangular aperture is a slightly rounded fold, the *levator cushion*, which is a prominence caused by the levator veli palatini muscle.

The prominence of the posterior lip facilitates the introduction of the Eustachian catheter, in connection with which the location of the aperture in the midlateral wall just above the level of the floor of the nasal fossa should be carefully noted. A fold of mucosa descending from the posterior lip of the aperture to the lateral pharyngeal wall is the *plica salpingopharyngea* (due to the m. salpingopharyngeus). An inconspicuous *plica salpingopalatina* descends from the anterior lip to the soft palate.

The **posterior wall** (fig. 876) of the nasal pharynx slopes from below upward and forward, passing (at the level of the anterior arch of the atlas) into the *roof* or *fornix* [fornix pharyngis]. The fornix is attached chiefly to the basioccipital and basisphenoid bones, extending laterally to the carotid canal of the pyramid, and anteriorly to the base of the nasal septum. The mucosa of the fornix and to a certain extent also of the posterior wall, especially in children, is thrown into numerous folds, which contain much lymphoid tissue, both diffuse and in the form of numerous characteristic lymphoid nodules, with crypt-like invaginations of the surface epithelium. This area constitutes the **pharyngeal tonsil** [tonsilla pharyngea] (fig. 907).

The pharyngeal tonsil is well developed in children (often abnormally enlarged, producing 'adenoids'), but usually, though not always, atrophied in the adult. According to Symington, the involution of the pharyngeal tonsil begins at 6 or 7 years, and is usually completed at 10 years. In the region of the pharyngeal tonsil and elsewhere, the mucosa presents numerous small racemose mucous glands, especially thick in the palatal floor of the nasal pharynx and similar to those of the oral cavity.

In the mucosa of this region, and closely associated with the pharyngeal tonsil, there is also found a small, inconstant blind sac, the *pharyngeal bursa*. A *'pharyngeal hypophysis'* apparently derived from the lower end of Rathke's pouch, has also been described as constantly present (fig. 1070).

The **oral pharynx** (figs. 876, 889, 907) is continuous *above* through the pharyngeal isthmus with the nasal pharynx and *below* with the laryngeal pharynx. Its *posterior* wall presents no special features. The *anterior* wall is deficient above, where there is a communication with the mouth cavity through the *isthmus faucium*. The faucial isthmus is bounded above by the uvula, laterally by the anterior (glossopalatine) arches, and below by the dorsum of the tongue in the region of the sulcus terminalis. Below the faucial isthmus, the anterior wall of the oral pharynx is formed by the root of the tongue, which has been described previously. The *lateral* wall of the oral pharynx on each side presents the *palatine tonsil*, enclosed in a somewhat triangular *tonsillar fossa* [sinus tonsillaris] limited anteriorly and posteriorly by the anterior and posterior palatine arches, and below by the root of the tongue.

The **palatine arches** (pillars) are folds of the mucosa formed at the sides of the free posterior border of the soft palate, as already mentioned in connection with that organ. The *anterior arch* [arcus glossopalatinus] extends from the soft

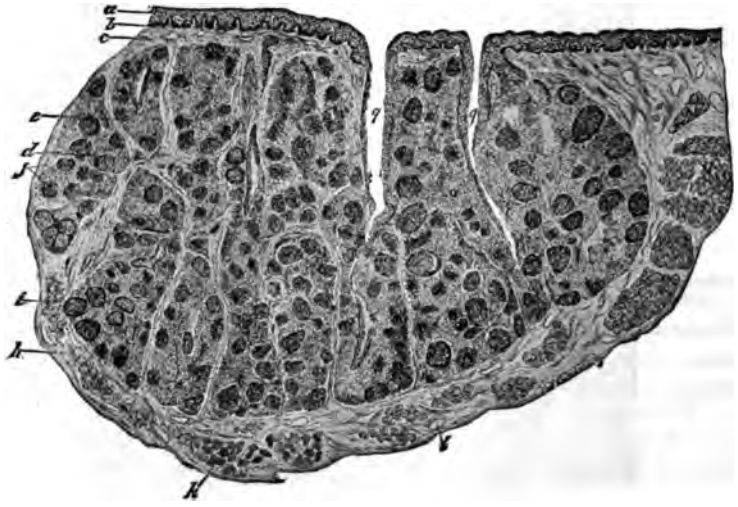
palate downward and forward to the lateral margin of the tongue, just behind the papillæ foliatæ. It is a fold of mucosa due to the underlying glossopalatine muscle, and inconspicuous except when this muscle is in action, or when the tongue is depressed. It forms the lateral boundary of the faucial isthmus. The *posterior arch* [arcus pharyngopalatinus] is a more prominent fold which extends from the soft palate in the region of the uvula downward and backward to join the posterolateral aspect of the pharyngeal wall. It forms the lateral boundary of the pharyngeal isthmus, and encloses the pharyngopalatine muscle, whose action will be explained later.

The Palatine Tonsil

The **palatine tonsil** [tonsilla palatina] (figs. 889, 908, 909) is a flattened ovoidal body, usually visible through the mouth cavity and faucial isthmus, and located on each side of the oral pharynx. The tonsil is extremely variable in size, but in the young adult averages 20 to 25 mm. in height, 15 to 20 mm. in width (anteroposteriorly) and about 12 mm. in thickness. The weight averages 1.4 grams (Gundobin).

The **lateral** or attached **surface** of the tonsil is covered by a thin but firm fibrous *capsule*, which is continuous with the pharyngeal aponeurosis, and in contact with the superior constrictor muscle of the pharynx (fig. 889).

Fig. 908.—Vertical Section of a Human Palatine Tonsil. *a*, Stratified epithelium; *b*, basement membrane; *c*, tunica propria; *d*, trabeculæ; *e*, diffuse lymphoid tissue; *f*, nodules; *h*, capsule; *i*, mucous glands; *k*, striated muscle; *l*, blood vessel; *g*, crypts. (From Radasch.



Just outside the constrictor, the tonsil is in relation with the ascending pharyngeal and ascending palatine arteries, but is separated by a considerable space from the external and internal carotids. Rarely, however, the lingual or external maxillary may extend up higher than usual, so as to be in close relation with the lower aspect of the tonsil. Further lateralward, the palatine tonsil is in relation with the internal pterygoid muscle, and on the surface corresponds to a point somewhat above and in front of the angle of the mandible. The posterior border of the tonsil is thicker than the anterior, and forms a somewhat flattened surface in contact with the pharyngopalatine muscle (fig. 909).

The **medial** or free **surface** of the tonsil is covered with mucosa and presents a variable number (12 to 30) small pits which are the openings into the tubular or slit-like *crypts* [fossulæ tonsillares]. These crypts are somewhat more numerous in the upper part of the tonsil, and are sometimes branched or irregular in form. Usually they end blindly in the substance of the tonsil, surrounded by lymphoid tissue in characteristic nodular masses (fig. 908).

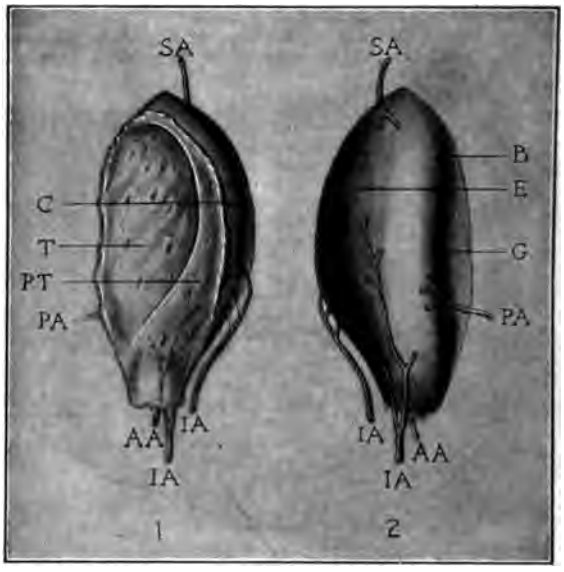
The lymphocytes normally migrate through the stratified squamous epithelium lining the crypts (occasionally eroding passages of considerable size), and escape into the pharyngeal and mouth cavities, where they form the so-called *salivary corpuscles*. Around the periphery of the palatine tonsil, within the capsule, are many mucous glands (fig. 908), similar to those described in connection with the lingual and pharyngeal tonsils. The ducts of the mucous glands sometimes enter the crypts, but usually pass to the surface chiefly around the margins of the palatine tonsil.

Tonsillar plicæ and fossæ.—Connected with the tonsil are certain important folds and fossæ. The *plica triangularis* (fig. 909) is a fold of variable extent and appearance, placed just behind the anterior arch, wider below and narrower above. According to Fetterolf, it is a prolongation of the tonsillar capsule, covered with mucosa. It may be adherent to the anterior part of the medial surface of the tonsil, or it may be free, in which case it covers a recess called the *anterior tonsillar fossa*. Occasionally there is a similar plica and fossa at the *posterior* border of the tonsil. Above the tonsil there is similarly a *supratonsillar fossa* [fossa supratonsillaris], which is also inconstant and exceedingly variable in size and shape. Killian found a supratonsillar fossa or canal in 41 of 105 cadavers.

Tonsillar vessels.—The *arteries* to the tonsil (figs. 492, 909) include the *anterior* tonsillar (from the dorsalis linguæ); the *inferior* tonsillar (from the external maxillary); the *posterior* tonsillar (from the ascending pharyngeal) and the *superior* tonsillar (from the descending palatine). These pierce the capsule and supply the gland. The *veins* form a plexus around the capsule and empty into the lingual vein and the pharyngeal plexus. The *lymphatic* relations of the palatine tonsil are important. *Afferent* vessels are received from adjacent areas of the mucosa in the pharynx, mouth and lower part of the nasal cavity (v. Lenart). These are connected with an extensive lymphatic plexus around the lymph follicles within the tonsil. *Efferent*

FIG. 909.—THE LEFT PALATINE TONSIL, SHOWING THE ARTERIAL SUPPLY.

1, Mesial aspect. 2, Posterolateral aspect. E, lateral surface. B, posterior surface. T, medial surface. G, groove for pharyngopalatine muscle. C, capsule. PT, plica triangularis. Arteries: AA, anterior tonsillar (from dorsal lingual); PA, posterior tonsillar (from ascending pharyngeal); SA, superior tonsillar (from descending palatine); IA, inferior tonsillar (anterior from dorsal lingual; posterior from tonsillar branch of internal maxillary). (Fetterolf: Amer. J. Med. Sc., 1912.)



lymphatic vessels pass chiefly to the upper deep cervical lymphatic nodes. One of these, located just behind the angle of the mandible, is so closely connected with the tonsil, and so constantly enlarged following tonsillar infection, that it has been called the *tonsillar lymph-gland* (Wood). There are also communications with the submaxillary and superficial cervical lymphatic nodes. The tonsillar lymphatic vessels connect also with those of the lingual tonsil in the root of the tongue.

The **innervation** of the palatine tonsil is from the middle and posterior palatine nerves, and from the tonsillar branches of the glossopharyngeal, forming a plexus, the *circulus tonsillaris*.

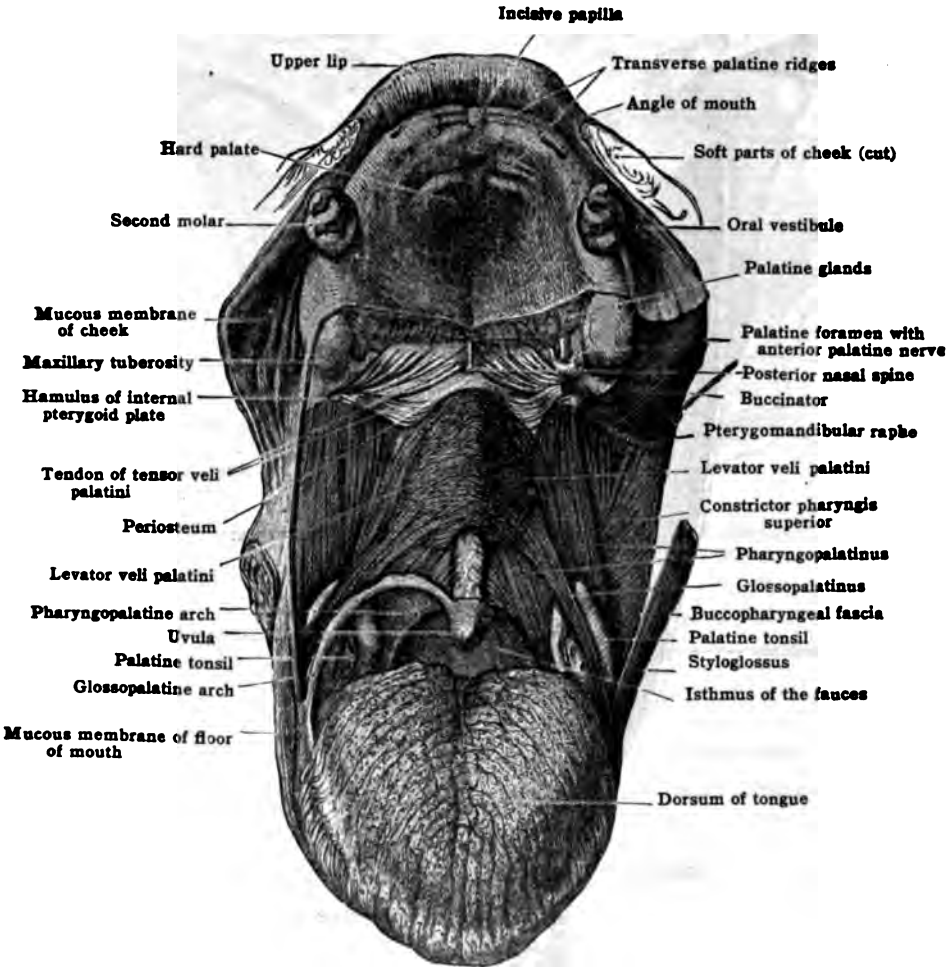
The tonsillar ring.—The two palatine tonsils, together with the lingual tonsil below and the pharyngeal tonsil above, form an almost complete ring of characteristic tonsillar tissue surrounding the pharynx and known as Waldeyer's 'tonsillar ring.' It is a highly specialized development of the diffuse lymphoid tissue which is found everywhere in the mucosa of the alimentary and respiratory tracts. It may be noted that the 'tonsillar ring' corresponds to the anterior limit of the embryonic foregut, hence the epithelium is of endodermic origin. The arrangement of the tonsils, together with their lymphatic connections, has suggested the widely accepted view that they are to be considered as protective mechanisms whose function is to intercept infectious material which has entered the mouth or nasal cavities. This theory is supported by the experiments of v. Lenart, who found that substances injected into the nasal mucosa are intercepted partly in the tonsils, and partly in the cervical lymph nodes. Oppel, however, opposes this view, holding that the function of the tonsils, as of lymphoid tissue elsewhere, is merely the production of lymphocytes.

Development of the tonsil.—For the development of the palatine tonsil in the floor of the second branchial pouch, see p. 42. The later fetal development of the tonsil is subject to

considerable individual variation. The supratonsillar fossa is a remnant of the upper part of the primitive sinus tonsillaris, which may be transformed into a canal by growth of adenoid tissue around it. It is inconstant and quite variable in size and extent. A portion of the sinus may likewise persist anteriorly (anterior tonsillar fossa) between the tonsil and the plica triangularis, but this portion is usually obliterated by fusion of the plica with the tonsil. The occasional retrotonsillar fold and fossa are said to arise secondarily (Hammar).

Variations in the tonsil.—The palatine tonsil, like the lingual and pharyngeal tonsils, is an exceedingly variable organ. Many of the variations are developmental in origin, as above indicated, and are therefore *congenital*. Furthermore, the tonsils, like all lymphoid structures, are subject to marked *age-variations* (see p. 36). Though fairly well formed at birth, they are yet somewhat undeveloped. They rapidly increase in relative size and complexity, however, being best developed in childhood. After the age of puberty, they usually undergo certain retrogressive changes, become smaller in size, and in old age become almost entirely atrophied and lost. They are also markedly subject to inflammatory hypertrophy, especially in children Variations in the relations of the *blood-vessels* were mentioned above.

FIG. 910.—THE MUSCLES OF THE SOFT PALATE AND THE PALATAL ARCHES AS SEEN FROM IN FRONT. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)

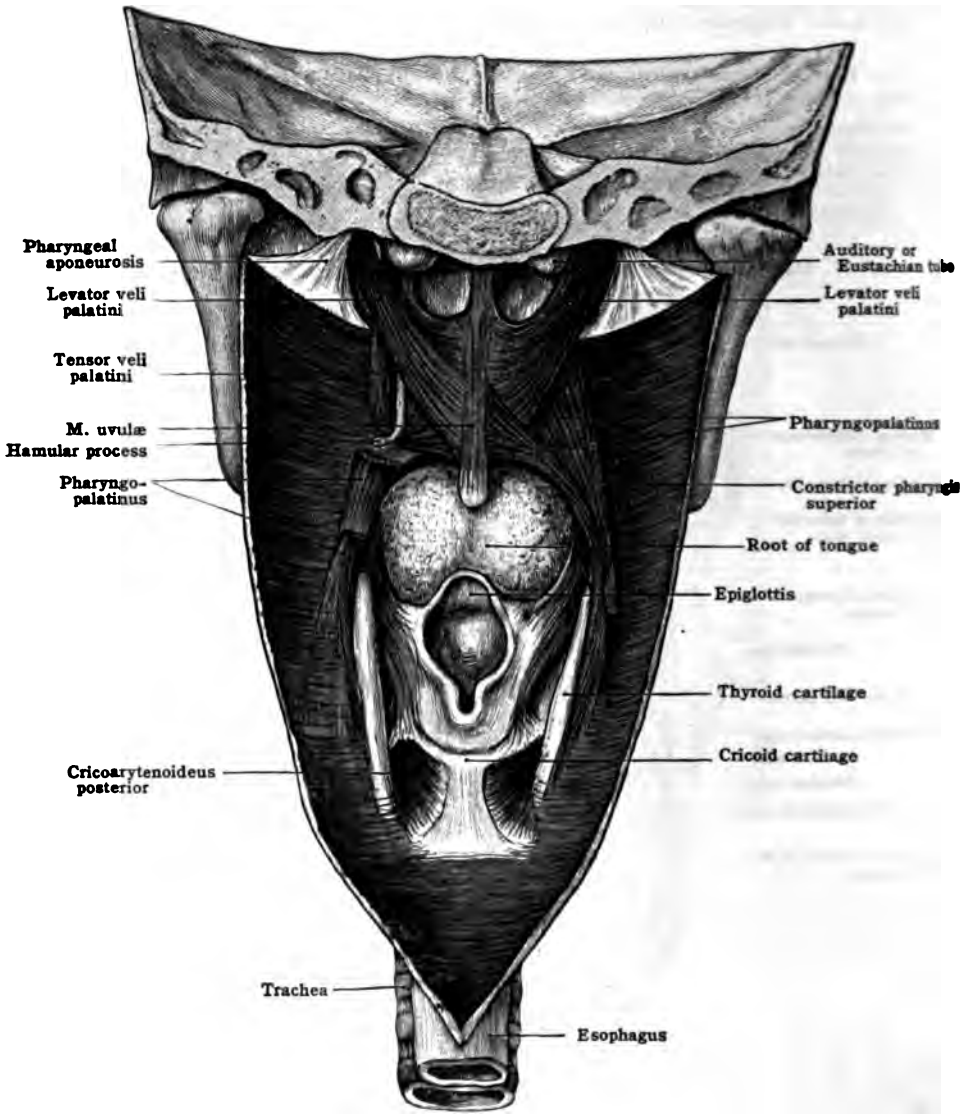


The laryngeal pharynx (fig. 876) is the lower portion leading from the oral pharynx above into the esophagus below (at the level of the lower border of the cricoid cartilage, usually opposite the sixth cervical centrum). It is wide above and narrow below (fig. 907). Its *posterior* walls are continuous with those of the oral pharynx and in relation with the vertebral centra. Its *lateral* walls are attached to the hyoid bone and the posterior part of the medial surface of the thyroid cartilage. *Anteriorly* it is in relation with the larynx (fig. 907). In the median line above is the epiglottis, below which is the superior aperture of the larynx. Still lower is the posterior wall of the larynx, containing the arytenoid and lamina of the cricoid cartilage. Laterally are the pharyngoepiglottic folds,

and below these on each side a deep, elongated fossa, the *recessus piriformis*, bounded laterally by the medial surface of the thyroid cartilage. The mucosa of the laryngeal pharynx is similar to that of the oral pharynx, and contains racemose mucous glands, which are especially numerous in its anterior wall.

Muscles of the pharynx and soft palate.—These muscles (figs. 910-912), which are here grouped together for convenience of description, are chiefly sphincter-like constrictors in function. They include the constrictors of the faucial isthmus (mm. glossopalatini), the constrictors of the pharyngeal isthmus

FIG. 911.—VIEW OF MUSCLES OF SOFT PALATE, AS SEEN FROM BEHIND, WITHIN THE PHARYNX. (Modified from Bourgery.)



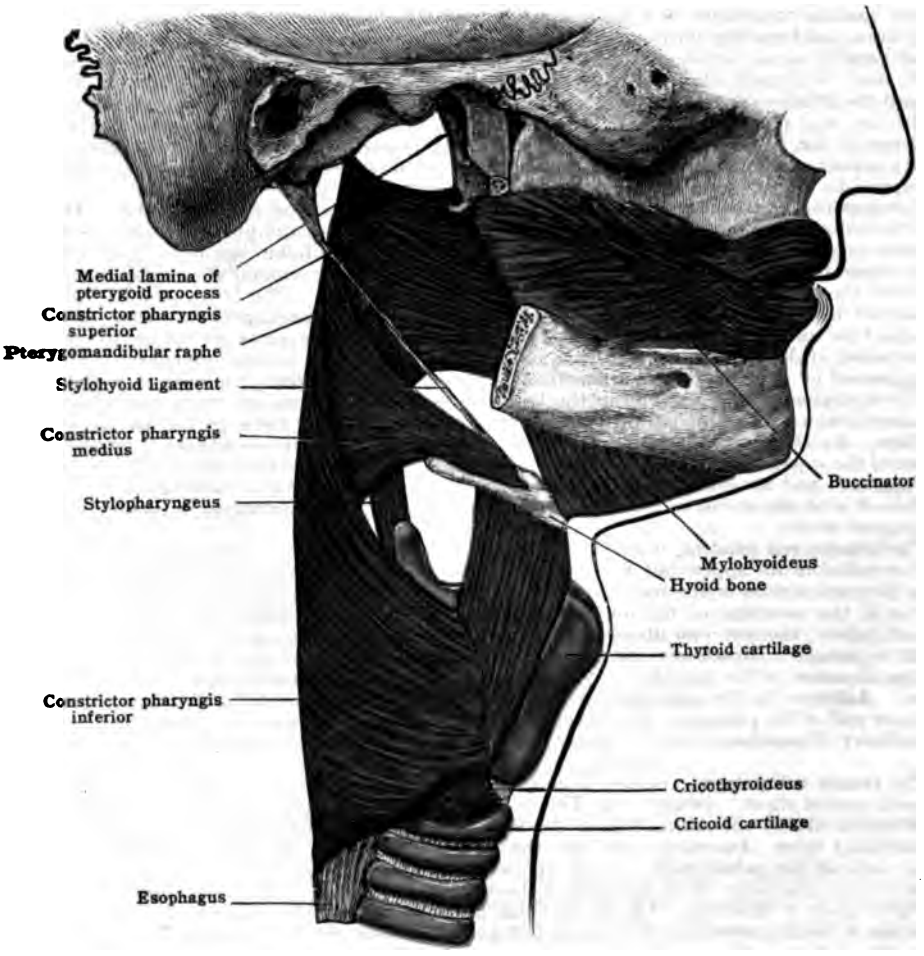
(mm. pharyngopalatini), the three pharyngeal constrictors, and also the levator and the tensor veli palatini, the m. uvulæ and the stylopharyngeus. The stylopharyngeus and pharyngopalatine muscles form an incomplete longitudinal layer within the more circularly arranged constrictors of the pharynx.

The muscles are arranged in layers either behind or in front of the palatal aponeurosis, and in a horizontal section of the soft palate the following layers are met with from behind forward: (1) The mucous membrane on the pharyngeal surface; (2) the posterior layer of the pharyngopalatinus (palatopharyngeus); (3) the m. uvulæ; (4) the levator veli palatini; (5) the anterior layer of the

pharyngopalatinus; (6) the palatal aponeurosis with the tensor veli palatini; (7) the glossopalatinus (palatoglossus); and (8) the mucous membrane on the oral aspect.

The glossopalatinus (palatoglossus) is a cylindrical muscle extending between the soft palate and the lateral border of the tongue. *Origin.*—From the oral surface of the palatal aponeurosis. *Insertion.*—(1) The superficial layer of muscles which covers the side and adjacent part of the under surface of the tongue; (2) the transversus linguæ. *Structure.*—At its origin the muscle forms a thin sheet, but the fibers, passing lateralward, quickly concentrate to form a cylindrical bundle, which passes downward beneath the mucous membrane of the pharynx and in front of the palatine tonsil, forming the glossopalatine arch of the fauces. It reaches the side of the tongue at the junction of its middle and posterior thirds, and some of its fibers continue forward to join with those of the styloglossus and hyoglossus, while the majority pass

FIG. 912.—THE MUSCLES OF THE PHARYNX, LATERAL VIEW.



medially to become continuous with the transversus linguæ. *Nerve-supply.*—From the pharyngeal branches (plexus) of the vagus. *Action.*—(1) To draw the sides of the soft palate downward; (2) to draw the sides of the tongue upward and backward. The combination of these actions tends to constrict the faucial isthmus. (The origin and insertion of the glossopalatinus as given above are often described as reversed.)

The **pharyngopalatinus** (palatopharyngeus)—named from its attachments—is a thin sheet. *Origin.*—(1) From the aponeurosis of the soft palate by two heads which are separated by the insertion of the levator veli palatini; (2) by one or two narrow bundles from the lower part of the cartilage of the auditory (Eustachian) tube (*salpingopharyngeus*). *Insertion.*—(1) By a narrow fasciculus into the posterior border of the thyroid cartilage near the base of the superior cornu; (2) by a broad expansion into the fibrous layer of the pharynx at its lower part. *Structure.*—The upper head of the muscle consists of scattered fibers which blend with the opposite muscle across the middle line; the lower head is thicker, and follows the curve of the posterior border of the palate. The two heads with the fasciculus from the auditory (Eustachian) tube form a compact muscular band in the posterior palatine arch; the fibers mingle with those of

the stylopharyngeus, at the lower border of the superior constrictor, and then expand upon the lower part of the pharynx. *Nerve-supply.*—From the pharyngeal branch (plexus) of the vagus. *Action.*—(1) Approximates the posterior arches of the fauces; (2) depresses the soft palate; (3) elevates the pharynx and larynx. (The origin and insertion above given are often described as reversed.)

The **inferior constrictor** [M. constrictor pharyngis inferior] is thick and strong. It *arises* from the thyroid cartilage immediately behind the oblique line and superior tubercle (thyropharyngeus), and from a tendinous arch extending between the inferior tubercle of the thyroid and the cricoid cartilage and also from the lateral surface of the cricoid cartilage (cricopharyngeus) (fig. 912). The fibers spread backward and medialward, the lowest horizontally, while those above ascend more and more obliquely, and are *inserted* into the fibrous raphé of the pharynx. Some of the lowest fibers are continuous with the muscular fibers of the esophagus, and the upper overlap the middle constrictor (fig. 912). The *nerve-supply* of all three constrictors is from the pharyngeal plexus.

Near the upper border the superior laryngeal nerve and artery pierce the thyrohyoid membrane to reach the larynx. The inferior laryngeal nerve ascends beneath the lower border immediately behind the cricothyroid articulation.

The **middle constrictor** is a fan-shaped muscle which *arises* from the lesser cornu of the hyoid bone and from the stylohyoid ligament (chondropharyngeus), and from the whole length of the greater cornu (ceratopharyngeus). The diverging fibers are *inserted* into the median raphé, and blend with those of the opposite side. The lower fibers of the muscle descend beneath the inferior constrictor, to the lower part of the pharynx; the upper overlap the superior constrictor, and reach the basilar process of the occipital bone, while the middle fibers run transversely (fig. 912). The glossopharyngeal nerve passes downward above its upper border, the stylopharyngeus passes between it and the superior constrictor, and near its origin it is overlapped by the hyoglossus and crossed by the lingual artery.

The **superior constrictor** is quadrilateral in shape, pale, and thin (figs. 374, 912). It *arises* from the lower third of the hinder edge of the medial lamina of the pterygoid process and its hamular process (pterygopharyngeus), from the pterygomandibular ligament (buccopharyngeus), from the posterior fifth of the mylohyoid ridge of the mandible (mylopharyngeus), and from the side of the root of the tongue (glossopharyngeus). The fibers pass backward to be *inserted* into the median raphé, the highest reaching the pharyngeal tubercle. The Eustachian tube and the levator veli palatini are placed above the superior arched border, and the space (*sinus of Morgagni*) between this and the basilar process, devoid of muscular fibers, is strengthened by the pharyngeal aponeurosis, this portion of it being semilunar in shape.

The **stylopharyngeus** *arises* from the base of the styloid process internally (figs. 490, 881). It passes downward and medialward to reach the pharynx between the superior and middle constrictors. Its fibers spread out as it descends beneath the mucous membrane. At the lower border of the superior constrictor some of its fibers join fibers of the pharyngopalatinus (palatopharyngeus), and are *inserted* into the posterior border of the thyroid cartilage (fig. 912); the rest blend with the constrictors. The *nerve-supply* of the stylopharyngeus is from the glossopharyngeal nerve.

The **levator veli palatini**—named from its action on the velum of the soft palate—is somewhat rounded in its upper, but flattened in its lower, half. *Origin.*—(1) The inferior surface of the petrous portion of the temporal, anterior to the orifice of the carotid canal; (2) the lower margin of the cartilage of the auditory (Eustachian) tube. *Insertion.*—The aponeurosis of the soft palate; the terminal fibers of the muscles of each side meet in the middle line in front of the m. uvulæ. *Structure.*—Its origin is by a short tendon; the muscle then becomes fleshy and continues so to its insertion. *Nerve-supply.*—From a pharyngeal branch (plexus) of the vagus. *Action.*—(1) To raise up the velum of the soft palate, and bring it in contact with the posterior wall of the pharynx; (2) to narrow the pharyngeal opening and to widen the isthmus of the auditory (Eustachian) tube. (According to Cleland, it closes the pharyngeal opening of this tube.)

The **tensor veli palatini**—named from its action on the velum of the soft palate—is a thin, flat, and narrow sheet. *Origin.*—(1) The scaphoid fossa of the sphenoid; (2) the angular spine of the sphenoid; (3) the lateral side of the membranous and cartilaginous wall of the auditory (Eustachian) tube. *Insertion.*—(1) Into the transverse ridge on the lower surface of the horizontal plate of the palate bone; (2) the aponeurosis of the soft palate.

Structure.—Its belly as it descends between the pterygoideus internus and the internal pterygoid plate is muscular. On approaching the hamular process it becomes tendinous, and continues so to its insertion. A bursa is interposed between the hamular process and the tendon. The belly of the muscle is at nearly a right angle with its tendon. *Nerve-supply.*—From the mandibular division of the trigeminus through the tensor veli palatini branch of the otic ganglion. *Actions.*—(1) Tightens the soft palate; (2) opens the auditory (Eustachian) tube during deglutition.

The **musculus uvulæ**—so named by reason of its position in the uvula. *Origin.*—(1) From the aponeurosis of the soft palate and tendinous expansions of the two tensores veli palatini. *Insertion.*—Into the uvula. *Structure.*—The muscle consists of two narrow parallel strips lying on each side of the middle line of the palate. *Nerve-supply.*—From the pharyngeal branches (plexus) of the vagus. *Action.*—To draw up the uvula.

Development of the muscles.—According to W. H. Lewis, the tensor veli palatini is a derivative of the mandibular arch (probably split off from the pterygoid mass); the levator veli palatini and m. uvulæ come with the facial musculature from the hyoid arch; the glossopalatine, stylopharyngeus and pharyngeal constrictors probably from the third visceral arch, in a premuscle mass visible in a 9 mm. embryo. The adult innervation of the pharyngeal muscles does not agree entirely with this, however. The pharyngeal muscles (as above stated) are innervated chiefly from the vagus, whereas if derived from the third arch their innervation from the glossopharyngeus would be expected.

Process of swallowing.—In the act of swallowing, practically all of the muscles of the mouth, tongue, palate and pharynx are involved. By compression of the lips and cheeks, together with elevation of the tongue, the food is forced backward through the faucial isthmus into the oral pharynx. Constriction of the faucial isthmus by the glossopalatine muscles assists in preventing a return to the mouth. By the action of the levator and tensor veli palatini, and pharyngopalatine muscles, the soft palate is retracted and tightened, with constriction of the pharyngeal isthmus, so as to prevent the passage of the food upward into the nasal pharynx. The pharynx is drawn upward by the stylopharyngeus, and the pressure produced by the pharyngeal constrictors (the contraction beginning above and extending downward) forces the food downward through the laryngeal pharynx and into the esophagus. Passage of the food into the larynx is prevented by constricton of the superior aperture of the larynx.

Vessels and nerves.—The vessels of the tonsil and the motor nerves of the various muscles have already been mentioned. In general, the *arteries* to the pharynx are derived chiefly from the ascending pharyngeal, the ascending palatine branch of the external maxillary, and the descending palatine and pterygopalatine branches of the internal maxillary. The *veins* form a venous plexus between the pharyngeal constrictors and the pharyngeal aponeurosis, and also an external plexus, communicating with the pterygoid plexus above and with the posterior facial or internal jugular vein below. The *lymphatic* vessels pass chiefly to the deep cervical nodes, those from the upper portion (including the pharyngeal tonsil) ending partly in the retropharyngeal nodes. The *nerves* of the pharynx, both motor and sensory, are derived chiefly from the glossopharyngeal and vagus, by way of the pharyngeal plexus.

The development of the pharynx.—For the development of the pharynx, including the branchial arches and pouches, and the pharyngeal tonsils, see p. 41.

Variations.—Variations in the palatine and pharyngeal tonsils and in the pharyngeal bursa have already been mentioned. Remnants of the visceral clefts may persist as aberrant diverticula or as 'branchial fistulæ' connected with the pharynx. Many additional *muscles* have been described, chiefly longitudinal muscles arising from the base of the cranium either by splitting of those normally present, or as separate slips. A detailed description of these may be found in Poirier-Charpy's work. Abnormally extensive fusion of the posterior arches of the palate with the walls of the pharynx may produce a congenital stenosis of the pharyngeal isthmus.

Comparative.—The pharynx is not distinctly separated from the mouth cavity in the lower vertebrates. It is the region containing the branchial or visceral clefts and is thus both respiratory and alimentary in function. The *nasal* pharynx, including the apertures of the auditory tubes, becomes distinct along with the nasal cavity when the palate is formed (from the reptiles upward). In the air-breathing vertebrates, the laryngeal aperture appears in the ventral wall of the pharynx just anterior to the beginning of the esophagus. Of the *tonsils*, the *pharyngeal* are the most primitive, being present in the roof of the pharynx in amphibia, well developed in reptiles, birds, and mammals (Killian). The *palatine* tonsils, on the other hand, are characteristic of mammals, being rarely absent, however (e. g., rat, guinea pig). From the embryological point of view, Hammar has classified the palatine tonsils in the various mammals under (1) the primary type (including rabbit, cat, and dog), in which the tonsil is formed from the embryonic tonsillar tubercle (described above under development of tonsil); and (2) the secondary type (including pig, ox, sheep and man), in which the tonsillar tubercle disappears and the tonsil is developed from the wall of the surrounding tonsillar sinus. Typical epithelial crypts (highly branched in the ox) are found only in the secondary type. The tonsil may form a single (lymphoid) lobe (cat, pig, rabbit) or may develop typically two lobes (ox, sheep, man), separated by the intratonsillar fold. There are great variations among different species as to relative size, number and character of folds, crypts, etc. The intimate relation of the epithelium with the underlying lymphoid tissue is characteristic and constant.

THE ESOPHAGUS

The **esophagus** [œsophagus] (figs. 913, 914) is that portion of the alimentary canal which extends from the pharynx to the stomach. It is a constricted portion of the canal, being narrowest at its commencement opposite the lower border of the cricoid cartilage. It is again somewhat contracted behind the tracheal bifurcation, and at its passage through the diaphragm, which is opposite the tenth or eleventh thoracic vertebra (figs. 913, 914).

In its course downward the esophagus follows the curve of the vertebral column until it finally passes forward in front of, and slightly to the left of, the aorta to gain the esophageal opening in the diaphragm. In addition to this curve it presents two lateral curvatures, one convex toward the left side at the root of the neck and in the upper part of the thorax, and the other concave toward the left in the lower part of the thorax where it leaves the vertebral column. It lies in the middle line at its commencement (usually opposite the sixth cervical vertebra), and again, at a lower level, opposite the fifth thoracic vertebra.

The following **average measurements** *in situ* (range in parenthesis), were observed by v. Hacker on male cadavers (females slightly less): Teeth to cricoid level, 14.9 (14–16) cm.; total esophagus, 25.0 (23–30) cm.; cricoid to tracheal bifurcation, 10.4 cm.; tracheal bifurcation to cardia, 14.6 (12–17) cm. The average width is about 2.0 cm.; but at the upper end only 1.3 cm., and at the lower end (hiatus esophageus), 1.6 cm.

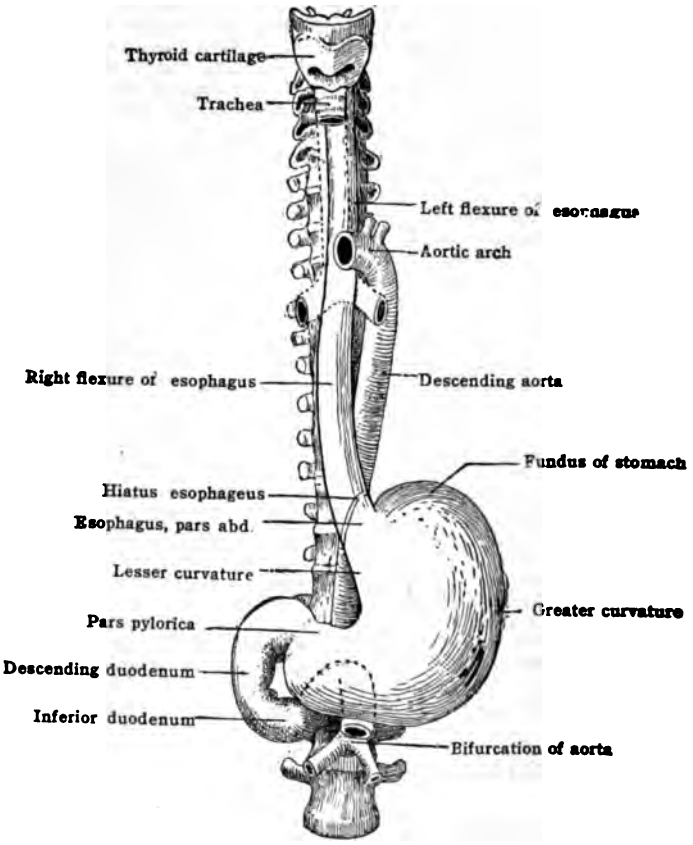
After death the esophagus is somewhat flattened from before backward, but it is more rounded during life. It is closed except during the passage of food, etc. The *peristaltic movements* of the esophagus can readily be observed by means of the Rœntgen-rays. Solids often

lodge a short time at the level of the arch of the aorta, but pass quickly through the cardiac orifice. A swallow of liquid, on the other hand, is usually detained at the lower end of the esophagus (probably by sphincteric action of the cardia) for about seven seconds before passing into the stomach (Pfahler).

The esophagus is divided into three parts: cervical, thoracic and abdominal.

Cervical portion.—The esophagus has anteriorly the trachea, the posterior portion of the left lateral lobe of the thyroid gland, and the left recurrent nerve, branches of the inferior thyroid artery, and the carotid sheath. *Posteriorly*, it rests upon the vertebral column, the longus colli muscles, and prevertebral fascia. *On its right side* are placed the right carotid and right recurrent nerve; and *on the left side* the left inferior thyroid vessels, left carotid artery, left subclavian, and the thoracic duct. The recurrent nerves pass upward on each side to gain the interval between the trachea and esophagus. The left nerve, as already described, lies in front of the tube, and the right along its right border.

FIG. 913.—THE ESOPHAGUS AND STOMACH. (Testut.)



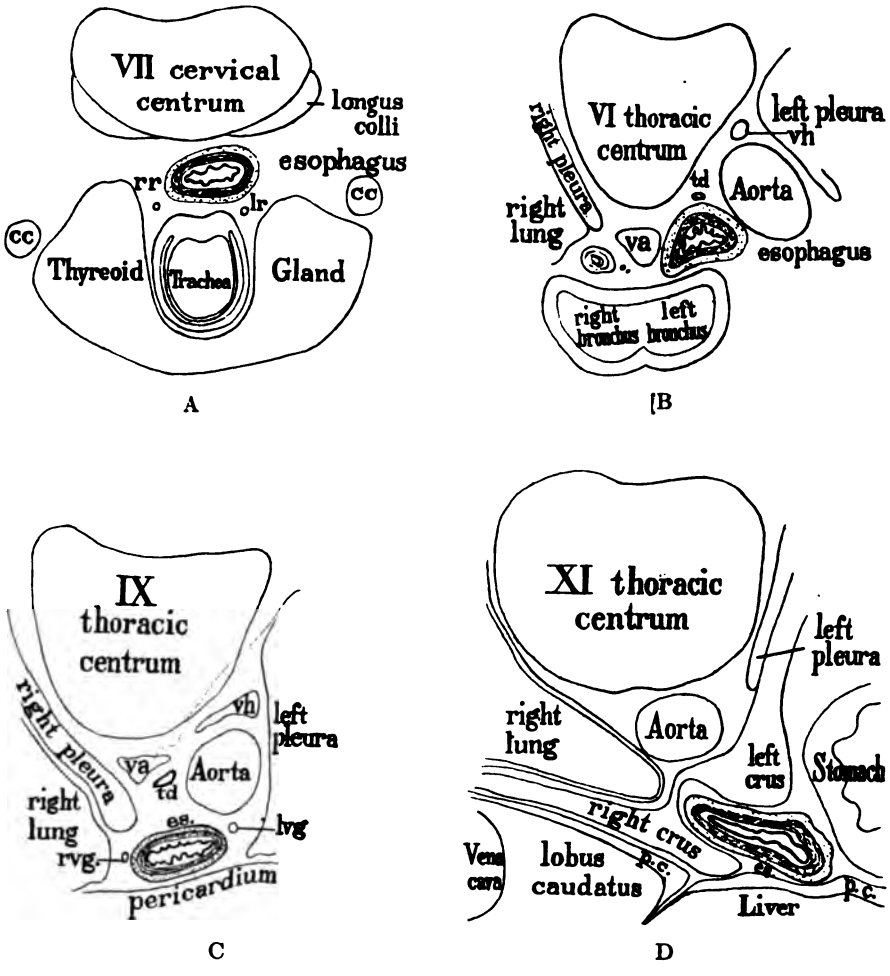
Thoracic portion.—The esophagus descends in the thorax through the superior and the posterior mediastina. In the *superior mediastinum* its anterior relations are the trachea, with the deep cardiac plexus in front of its bifurcation, the left subclavian and carotid arteries crossing its left border obliquely, the left recurrent nerve, and the arch of the aorta. To the *left* are the left carotid and subclavian arteries, the end of the arch of the aorta, and the left pleural sac. To the *right* it is in relation with the right vagus nerve and the right pleural sac. *Posteriorly*, it rests upon the vertebral column, the left longus colli muscle, and it overlaps the thoracic duct. As it enters the *posterior mediastinum* it passes behind the bifurcation of the trachea (or left bronchus) and the right pulmonary artery, resting posteriorly on the vertebral column and thoracic duct. In the posterior mediastinum it has *anteriorly* the pericardium, which separates it from the left atrium and a portion of the diaphragm; *posteriorly* it rests upon the vertebral column, accessory hemiazygos and hemiazygos veins, the right aortic intercostal arteries, the thoracic duct, and the descending aorta. To the *right* is the right pleural sac, the vena azygos, which it partly overlaps, and below, the thoracic duct. To the *left* in the upper part is the descending thoracic aorta, and, below, the left pleural sac is separated from it by a little loose areolar tissue. It is surrounded by the esophageal plexus formed by the vagus nerves, and, as they emerge from the lower part of the plexus, the left vagus lies in front of the esophagus and the right vagus behind.

Abdominal portion.—The terminal portion of the esophagus lies below the diaphragm, at the level of the xiphoid process, just to the left of the midline. *Anteriorly* is the left lobe of the liver; to the *left* the left lobe of the liver and the fundus of the stomach; to the *right* the

caudate (Spigelian) lobe of the liver; and *posteriorly* the decussating fibers of the crura of the diaphragm and the left inferior phrenic artery. The abdominal portion is very short, usually not more than 2 cm. (⅘ inch) in length (see figs. 914D, 929). According to Lerche, this portion of the esophagus is comparable to the pyloric canal of the stomach.

Structure.—The thick-walled esophagus presents the four typical tunics of the alimentary canal (fig. 915). The mucosa and the muscularis are the most important, the submucosa and the external adventitia being accessory layers. The **mucosa** (fig. 915) is thick and strong, of reddish color in its upper portion and more grayish below. It presents deep longitudinal folds to allow for distention, and when empty the lumen is therefore stellate in cross-sections. The lamina propria presents numerous papillæ, and is limited externally by a *muscularis mucosæ*. This is a comparatively thick layer (except at the upper end) and is composed of smooth muscle-fibers, longitudinally arranged.

FIG. 914.—CROSS SECTIONS SHOWING THE RELATIONS OF THE ESOPHAGUS AT VARIOUS LEVELS.



The submucosa (fig. 915) is a thick, very loose fibrous layer connecting the mucosa with the muscularis. It contains numerous vessels and nerves, and *mucous glands*. The latter [gl. œsophageæ] are of the racemose type, like those of the mouth, and are variable in number. There are also two sets of *superficial* glands, confined to the lamina propria, and resembling the fundus glands of the stomach. The upper set (Rüdinger-Schaffer glands) are found in 70 per cent. of cases, occurring above the level of the fifth tracheal ring. The lower set (esophageal cardiac glands) form a ring around the esophagus just above the cardiac aperture. A few small lymph nodes also occur in the sunmucosa, often around the ducts of the mucous glands.

The **muscularis** (fig. 915) is a thick reddish tunic with two distinct layers, approximately equal in thickness. The fibers of the *inner* layer are arranged circularly and are continuous with the inferior constrictor above and with the oblique fibers of the stomach below. The fibers of the *outer* layer are longitudinal and commence above as three flattened bands: a strong anterior band arising from the ridge on the back of the cricoid cartilage, and two lateral bands blending with the fibers of the stylopharyngeus and the pharyngopalatine. These all unite into a continuous layer which below passes into the muscular coat of the stomach. The upper third or fourth of the esophagus contains exclusively cross-striated muscle fibers, like those

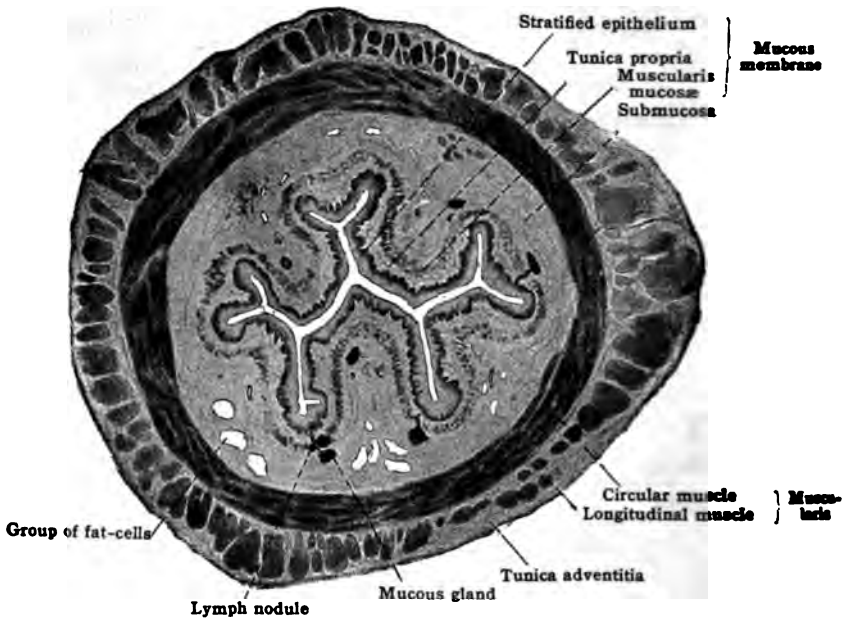
of the pharynx. Below this, there is a zone of intermingled smooth and cross-striated fibers. The lower half of the esophagus muscle is usually composed exclusively of smooth fibers.

Around the muscular coat is a thin loose *fibrous* layer [tunica adventitia] connecting the esophagus with neighboring structures.

Vessels and nerves.—The *arterial* supply of the esophagus is derived from the inferior thyroid, the esophageal branches of the aorta, the intercostals, the inferior phrenic and the left gastric arteries. Branches pierce the wall and supply the various coats. The *veins* accompany the arteries. They form on the outer surface of the esophagus a venous plexus opening into the gastric coronary vein below and the azygos and thyroid veins above (thus establishing a communication between portal and systemic veins). There are also numerous *lymphatics* in the esophagus arising chiefly in the mucosa and draining into the lower deep cervical, posterior mediastinal and superior gastric nodes (fig. 612). The *nerves* form two sympathetic plexuses, the submucous and the myenteric, from which the walls are supplied as will be described later for the stomach and intestine. Branches are received from the sympathetics, and from the vagus, including the recurrent nerve.

Development.—The embryonic esophagus is at first relatively very short, but lengthens rapidly in connection with the descent of the stomach. It is relatively longer in the newborn than in the adult (Kolster). The upper end is still high in children, corresponding to the

FIG. 915.—TRANSVERSE SECTION OF THE UPPER THIRD OF THE HUMAN ESOPHAGUS. X 5. (Lewis and Stöhr.)



higher vertebral level of the larynx. The primary longitudinal folds of the mucosa appear early (third month) and at the lower end seem to participate in the rotation of the stomach (F. P. Johnson). The superficial esophageal glands appear about the fourth month (78 mm.), the deep glands at 240 mm. (Johnson). Of the muscular layers, the circular appears first (at about 10 mm.), the longitudinal slightly later (17 mm.).

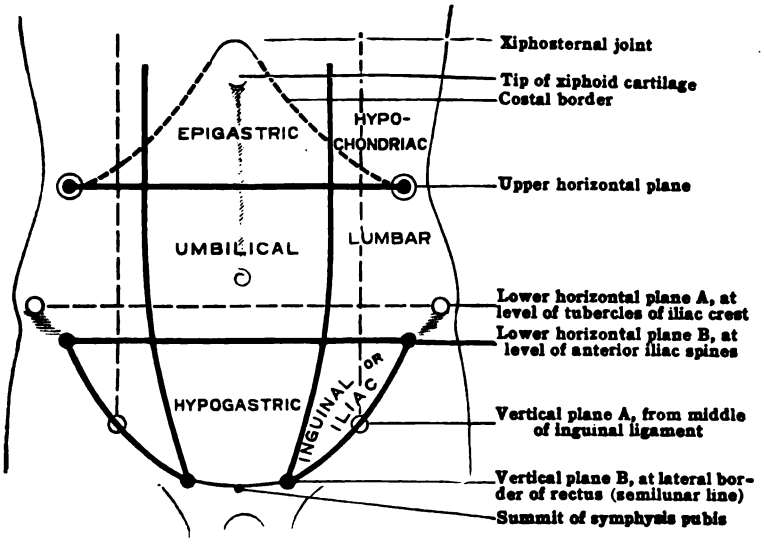
Variations.—Usually a bundle of smooth *muscle* connects the esophagus with the left bronchus [m. bronchoœsophageus], and another similarly with the left mediastinal pleura [m. pleuroœsophageus]. More rarely there are similar bands connecting with the trachea, pericardium, etc. Pouch-like *dilatations* of the esophagus may occur, especially in the upper part of its posterior wall or at the lower end. According to C. R. Robinson, the latter include (1) *ampulla phrenica*, just above the diaphragm, and (2) *antrum cardiacum*, in the abdominal portion of the esophagus. *Diverticula* also occur, some of which may be derived from the embryonic vacuolization of the epithelium previously described, as may likewise the occasional congenital *atresia*. Abnormal *strictures* of the esophagus may occur, oftenest at the upper end, at the left bronchus, and near the lower end. Finally, the esophagus may be in part either double or absent, and may communicate by fistula with the trachea.

Comparative.—The *length* of the esophagus varies with the length of the neck, being shortest in fishes and amphibia where the esophagus is not well marked off from the stomach. *Mucous glands* are absent in fishes, but occur typically in all higher forms. They are found best developed toward the lower end of the esophagus, except in mammals, where they are usually more numerous at the upper end. *Dilatations* may occur normally, as in the crop of birds, which is richly supplied with glands. The *musculature* of the esophagus is primitively entirely smooth (Oppel) as found in amphibia, reptiles and birds. A secondary replacement by cross-striated muscle is found to a variable extent in the majority of mammals and fishes.

THE ABDOMEN

The **abdomen** proper consists of that part of the body situated between the thorax and the pelvis. It is limited *above* by the diaphragm; *below*, by the brim of the true pelvis; *behind*, by the vertebral column, diaphragm, quadratus lumborum and psoas muscles, and by the posterior portions of the ilia. *At the sides* it is limited by the anterior parts of the ilia and the posterior portions of the muscles which compose the anterior abdominal wall, viz., the transversus, internal oblique, and external oblique. *In front*, besides these muscles, there are the two recti and pyramidales muscles. External to the peritoneum the abdomen is lined by a special layer of fascia. In a broad sense, the term abdomen is also used to include the pelvis, with which it is directly continuous below.

FIG. 916.—DIAGRAM OF THE ABDOMINAL REGIONS. Old method in broken lines. New method (BNA) in solid lines.

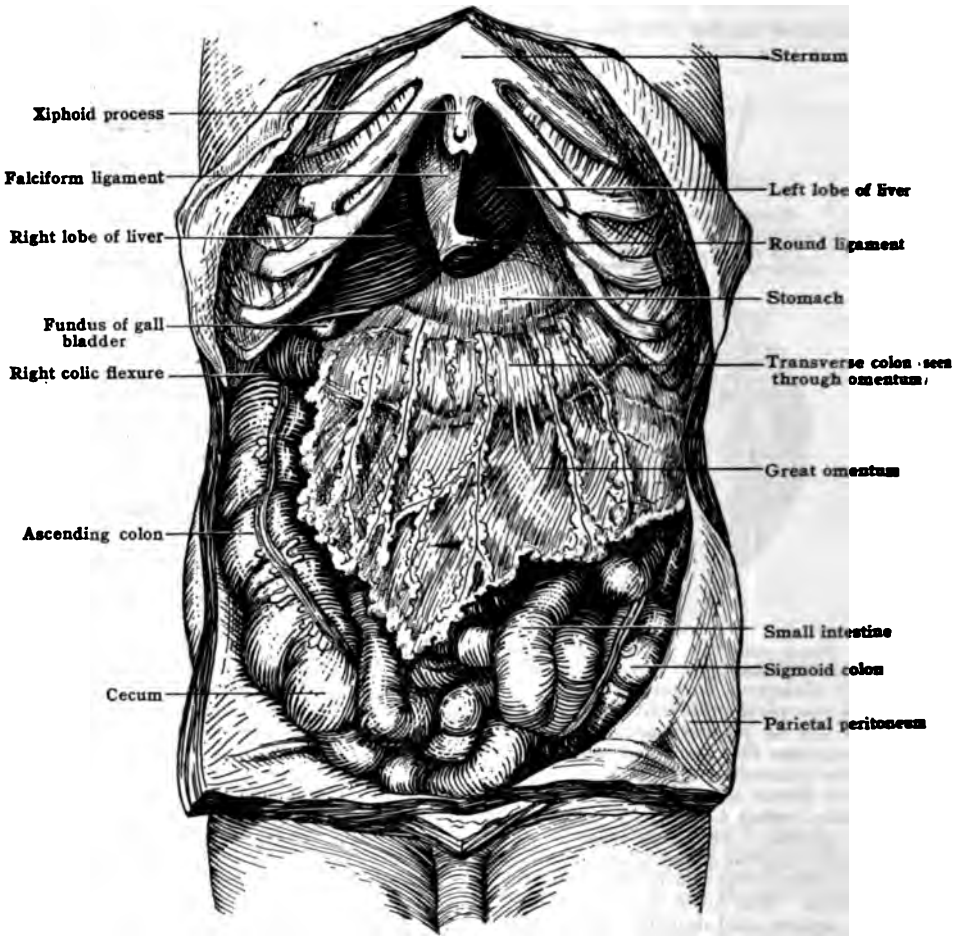


Abdominal regions.—For purposes of description, it is customary to divide the ventral surface of the abdomen, by means of two horizontal and two vertical lines, into nine regions (fig. 916). A complete uniformity in the use of the boundary lines marking these regional subdivisions has not as yet been attained, although the variations in the schemes used are not marked as concerns the main features. It should be borne in mind that the boundary lines used should be converted into planes, carried through the whole depth of the abdomen and defined on the dorsal as well as the ventral surface, and that the relations defined can only be approximate, owing to the wide range of the physiological variation in the position of the abdominal contents. The nine regions or subdivisions may be outlined as follows: The upper horizontal line or plane passes through the lowest point of the tenth costal cartilages. This lies about 3 to 5 cm. above the umbilicus, and passes dorsally through the second or third lumbar vertebra. The lower horizontal line and plane pass through the level of the anterior superior iliac spines, and dorsally about 2.5 cm. below the promontory of the sacrum. Cunningham has proposed that this line be passed through the tuberculum cristæ, therefore in a plane slightly higher than the interspinous plane. For the longitudinal lines and planes it has been customary to run vertical lines parallel with the midbody line or midsagittal plane, and from the middle of the inguinal ligaments. The preferable plan (BNA) is to use for this purpose the semilunar lines (lateral margin of the rectus muscle) extending from the costal border to the pubic spine on each side. This leaves on each side an inguinal region which includes the whole of the inguinal canal. The boundary lines here indicated may be made intelligible by a reference to fig. 916. The regions thus outlined are known as the right and left hypochondriac and epigastric regions, found above the upper horizontal line; the right and left lumbar and the umbilical regions, found between the two horizontal lines; the right and left inguinal or iliac and the hypogastric regions, found below the lower horizontal lines. According to the BNA, the lumbar regions are termed 'lateral abdominal.'

On laying open an abdomen from the front, the general form of the space is seen to be an irregular hexagon, the sides of which are formed as follows (fig. 917): The upper two by the margins of the costal cartilages with the xiphoid cartilage between; the two lateral sides by the edges of the lateral boundary; and the two lower by the two inguinal ligaments which extend to the pubes.

In this irregular hexagon the following organs can be observed without disarranging their normal position. Above, on the right side, under the costal cartilages, can be seen the liver, which extends from the right across the median line to a point below the left costal cartilages. Below the liver, and lying to the left side, can be seen the anterior surface of the stomach; from the lower border of the stomach the omentum extends downward, and shining through it can be seen the middle part of the transverse colon. On each side and below the irregularly folded omentum are exposed the coils of the small intestine; in the right iliac fossa appears a part of the cecum, above which extends the ascending colon; and on the left side part of the descending colon and the sigmoid colon.

FIG. 917.—ABDOMINAL VISCERA IN SITU. Ventral view. (After Toldt.)



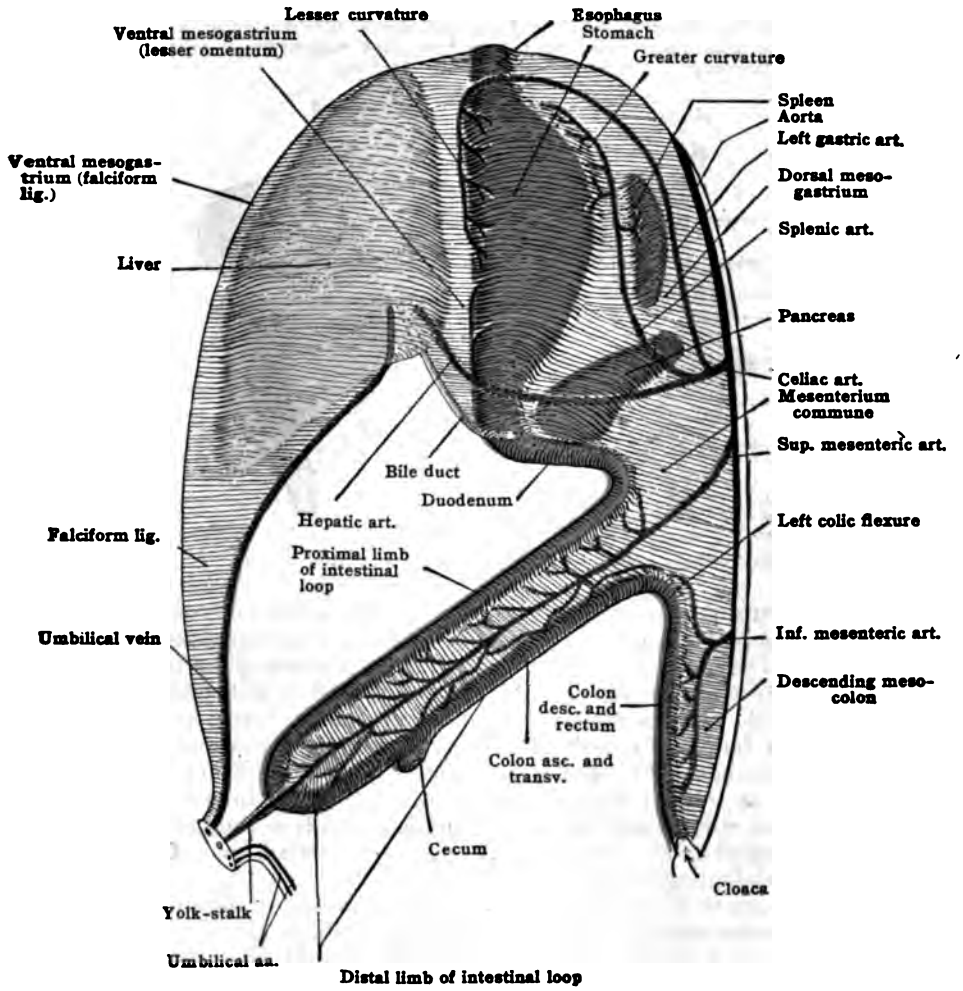
To the left of the stomach and under cover of the lower ribs of the left side the edge of the spleen may possibly be observed; and just below the edge of the liver, and about the level of the tip of the right ninth rib, the gall-bladder may be seen. The vertex of the urinary bladder may be noticed just behind the symphysis pubis and in the median line.

General morphogenesis.—Before taking up the various individual organs included in the abdominal and pelvic portions of the alimentary canal, a brief consideration of their general morphology is desirable. The primitive canal, as already described in the early embryo (in the section on DEVELOPMENTAL ANATOMY), and as found in the lower vertebrates is a comparatively straight, simple tube extending ventral to the body axis from mouth to anus. In the abdominal region (and primitively throughout the whole trunk), the canal lies within the body-cavity (celom), which is lined by parietal peritoneum. The visceral peritoneum is reflected from the mid-dorsal line as a double layer, the *primitive dorsal mesentery* [mesenterium commune] (fig. 918), within which the vessels and nerves pass to the walls of the canal. Within the dorsal mesentery are also the spleen and pancreas. In the anterior (upper) region of the abdomen there is also a similar primitive *ventral* mesentery, which contains the liver.

The relations above mentioned are indicated diagrammatically in fig. 918, which represents a comparatively early stage in the development of the intestinal canal. The liver is already somewhat separated from the diaphragm (with which it was intimately associated in the earlier septum transversum) (fig. 963). The ventral mesentery persists in the form of (1) the lesser omentum, connecting the stomach with the liver; and (2) the falciform ligament, connecting the liver with the ventral body-wall.

The stomach undergoes a rotation on its longitudinal axis so that its anterior border (lesser curvature) is turned to the right, and its posterior border (greater curvature) to the left (fig. 919). Thus the dorsal mesentery of the stomach [mesogastrium] bulges to the left and forward, carrying with it the spleen and pancreas. The portion of the mesentery corresponding to the pancreas, and that from the spleen to the root of the mesentery, become fused with the posterior

FIG. 918.—DIAGRAMMATIC REPRESENTATION OF AN EARLY STAGE IN THE DEVELOPMENT OF THE ALIMENTARY CANAL AND THE PERITONEUM (side view). (After Sobotta-McMurrich.)



body-wall (fig. 921). The portion of the primitive mesogastrium between the stomach and spleen persists as the *gastrolienal ligament*, while the lower portion arches forward and downward as an extensive fold, the *great omentum* (figs. 919, 922). The upper part of the dorsal layer of the great omentum soon fuses with the transverse mesocolon; while the lower portion later fuses with the adjacent ventral layer of the great omentum, converting this part of the omentum into the single apron-like fold found in postnatal life (figs. 917, 919, 922). The part of the great omentum extending from the greater curvature to the transverse colon forms the adult *gastrocolic ligament*. The portion of the peritoneal cavity left behind the stomach is termed the *bursa omentalis*, or lesser sac, the remainder of the peritoneal cavity being the greater sac. The two sacs communicate through the *epiploic foramen* (of Winslow) (figs. 921–923).

Along with the pancreas, the duodenum becomes adherent to the posterior wall. The remainder of the intestine forms a loop (figs. 918, 919), the upper portion of which forms the jejuno-ileum, the lower portion the large intestine. The intestinal loop rotates around the superior mesenteric artery as an axis, so that the cecum and ascending colon are carried over to the

right side of the body-cavity, where (with the corresponding portion of the primitive mesentery) they become adherent to the posterior body-wall (figs. 919, 920). The mesentery of the transverse colon persists (though becoming fused partly with the great omentum). The descending colon becomes displaced to the left side, and (together with its mesentery) becomes adherent to the posterior wall of the abdomen (figs. 919B, 920, 1016). The mesentery of the sigmoid colon usually persists (in part), while that of the rectum is obliterated. Through these modifications of the peritoneum, and through unequal growth in the different regions, the simple primitive intestinal tube is transformed into the complicated adult canal. The details of the transformation will be more fully discussed later, with the development of the intestines.

Under certain rare conditions, the developmental process is modified so as to produce *situs inversus*, which may be partial or complete, involving both thoracic and abdominal viscera. In this case, the viscera are transposed, the right and left sides being reversed.

(McMurrich after Hertwig.)

THE PERITONEUM

The **peritoneum** is a serous membrane which lines the body-cavity from the diaphragm to the pelvic floor, and invests or covers to a varying extent the viscera of the abdominal cavity. It may be regarded as a closed sac, the inner surface of which is smooth, while the outer surface is rough and is attached to the tissues which surround it. In the male subject the peritoneum forms actually a closed sac; but in the female its wall exhibits two minute apertures, which correspond to the openings of the Fallopian tubes. That part which lines the walls of the abdomen is termed the *parietal* peritoneum; that which is reflected on to the viscera is the *visceral* peritoneum. The disposition of the peritoneum in the adult may be studied first by noting its arrangement as made evident in transverse sections of the abdomen at certain levels.

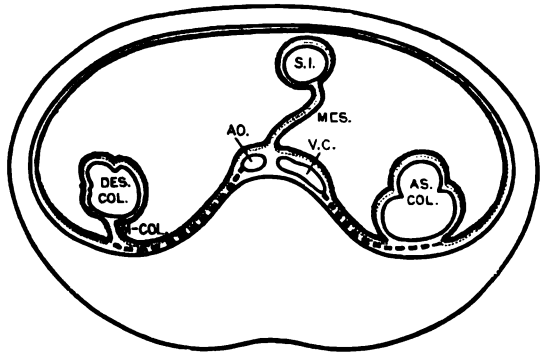
The first section to be described shows the peritoneum in its simplest relations. This is a transverse section through the body, at about the level of the fourth lumbar vertebra, and therefore about the site of the umbilicus (fig. 920).

Starting on the inner surface of the anterior abdominal wall, the peritoneum covers the transversalis fascia and the anterior abdominal muscles; then, passing to the left, it lines the side of the abdomen, until it reaches the descending colon. This it covers, as a rule, in front and on the sides, though occasionally it forms a mesocolon. Then it passes over the bodies of the vertebræ with the large vessels upon them, and leaves the back of the abdomen to run forward and enclose the small intestine, returning again to the spine. The two peritoneal layers thus form the mesentery, having between them a middle layer [lamina mesenterii propria] containing the terminal branches of the superior mesenteric vessels. It then passes over the right half of the posterior abdominal wall, covering the ascending colon in front and at the sides only (unless there be a mesocolon), and then passes on to the side and front of the abdomen to the point from which it was first traced. The areas of peritoneal reflection from the posterior wall are well shown in fig. 923.

In tracing the peritoneum in a transverse section of the body opposite the stomach (fig. 921), on a level about the first lumbar vertebra, its course becomes more complicated and difficult to follow.

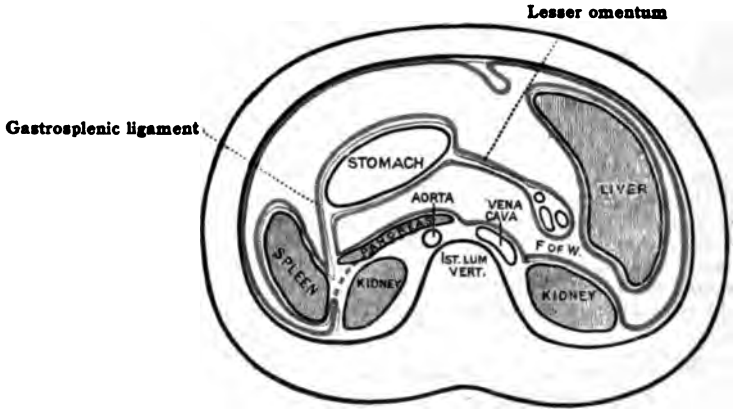
In the section already described, the peritoneum as a simple closed sac can be readily understood; but at the level now exposed the serous membrane has been so introverted (in connection with the primitive rotation of the stomach, as explained above) that there appear to be two sacs, one leading from the other, and known respectively as the greater and the lesser sac of the peritoneum. The *lesser sac* [bursa omentalis] is situated behind the stomach, so that on first opening the abdomen no trace of it is seen. The vestibule [vestibulum bursæ omentalis] is the portion which lies just behind the lesser omentum, and communicates with the greater sac through the epiploic foramen. The extensions upward and downward will be described later, in the sagittal section. In general, the lesser sac is limited *anteriorly* by the liver, stomach, and omenta; *posteriorly* by the posterior abdominal wall and the transverse mesocolon (fig. 922).

FIG. 920.—DIAGRAM OF CROSS-SECTION OF THE ABDOMEN, SHOWING THE PERITONEAL RELATIONS AT THE LEVEL OF THE UMBILICUS. *AO*, Aorta. *AS. COL.*, Ascending colon. *DES. COL.*, Descending colon. *MES.*, Mesentery. *M. COL.*, Descending mesocolon. *SI*, Small intestine. *V.C.*, Vena cava inferior. Peritoneum red; dotted lines indicate sites of obliteration.



The **epiploic foramen (foramen of Winslow)** (figs. 921–924) is situated just below the liver, and will readily admit one or two fingers. It is bounded *superiorly* by the caudate lobe of the liver; *inferiorly*, by the duodenum (pars superior); *posteriorly*, by the vena cava; and *anteriorly* by the right margin of the lesser omentum, containing the root-structures of the liver (bile-ducts, hepatic artery and portal vein). Through the epiploic foramen, the greater sac communicates with the lesser sac which extends to the left.

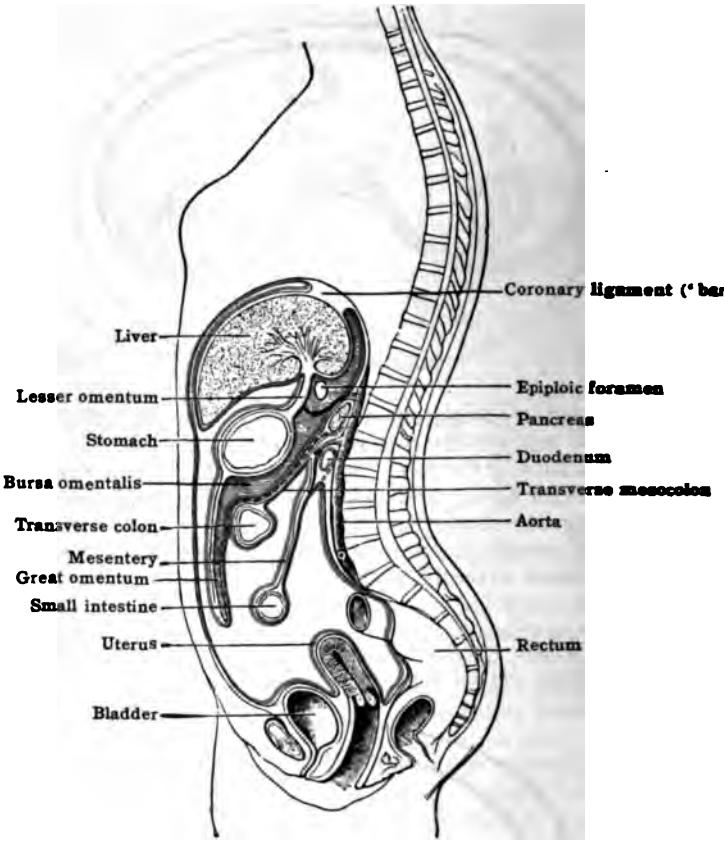
FIG. 921.—DIAGRAM OF CROSS-SECTION OF THE ABDOMEN, SHOWING THE PERITONEAL RELATIONS AT THE LEVEL OF THE EPIPLOIC FORAMEN OF WINSLOW (F. of W.). Peritoneum of greater sac in red; lesser sac (bursa) blue; dotted lines indicate site of obliteration.



The peritoneum may now be traced in a transverse section of the body at the level of the epiploic foramen (fig. 921), which is opposite the last thoracic or first lumbar vertebra. Starting at the front of the abdomen and going to the right, the peritoneum is seen to line the anterior abdominal wall, and to be reflected over the falciform ligament and ligamentum teres. It then passes backward over the side of the abdomen, and covers the front of the right kidney. It then extends on to the vena cava, when it enters the epiploic foramen and becomes a part of the lesser sac. Then it passes along the lesser sac, over the aorta and pancreas, which separate it from the vertebral column. Next it approaches the gastric surface of the spleen near the

hilus. Here it meets with another layer of peritoneum, and helps to form the phrenolienal and gastrolienal ligaments. Leaving the spleen, it passes forward and runs to the greater curvature of the stomach, forming the inner layer of the gastrolienal ligament. It now continues to the right, covering the posterior surface of the stomach, and leaves its medial border (lesser curvature) to form the posterior layer of the lesser omentum. At a slightly higher level, it passes upward and to the right to the liver. In this transverse section it merely passes around the right (free) margin of the lesser omentum, where it forms the anterior boundary of the epiploic foramen. Here it encloses the hepatic vessels and bile-duct, continuing to the left as the anterior layer of the lesser omentum. Then passing to the left it again reaches the stomach at the lesser curvature, and extends over its anterior surface to the greater curvature. It thus forms the outer layer of the gastrolienal ligament, and once more reaches the spleen. It now

FIG. 922.—DIAGRAM OF A SAGITTAL SECTION OF THE TRUNK, SHOWING THE RELATIONS OF THE PERITONEUM. Greater sac in red; lesser sac (bursa) in blue; dotted lines indicate sites of obliteration.



passes around the spleen to the region behind the hilus, where it is reflected on to the left kidney as the outer layer of the phrenolienal (lienorenal) ligament (fig. 922). The peritoneum then passes along the side and front of the abdomen to the point from which it started. In this section the liver is so divided as to appear separated from all connection with the other viscera and the abdominal wall, and to be surrounded by peritoneum. At a slightly higher level its peritoneum would join with that of the lesser omentum medially and that of the falciform ligament anteriorly, in accordance with the location of the liver in the primitive ventral mesogastrium (fig. 918).

The course of the peritoneum in a **longitudinal (midsagittal) section of the body** will now be considered (fig. 922).

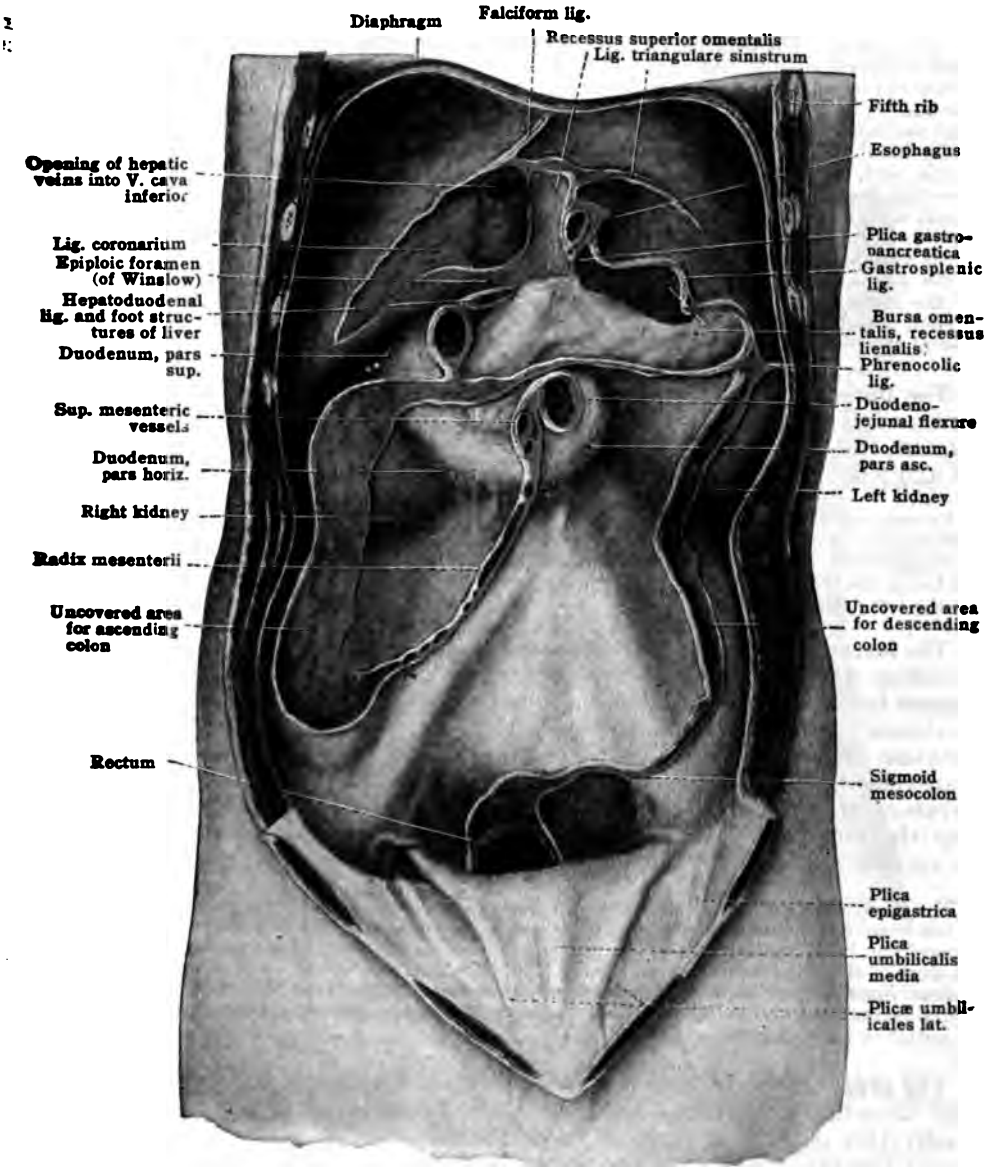
Starting at the umbilicus and passing downward, the peritoneum is seen to line the anterior abdominal wall. For some little way above the pubis the peritoneum is loosely connected with the abdominal wall, and the distended bladder can detach it to some extent.

On reaching the pubis it is reflected onto the upper surface of the bladder, covering it in the male as far back as the base of the trigone. Thence it is reflected onto the rectum, which it covers in front and at the sides on its upper part. Between the bladder and rectum it forms in the male the **rectovesical pouch** [excavatio rectovesicalis]. In the female the peritoneum is reflected from the bladder onto the uterus, forming the *vesicouterine* pouch [excavatio vesicouterina]. It then covers the uterus and extends so far down in the pelvis as to pass over the

[illegible]per part of the vagina behind. Thence it extends to the rectum as the **rectouterine pouch,** or [illegible]ch of Douglas [excavatio rectouterina; cavum Douglasi]. The membrane has now been [illegible]ced back to the posterior pelvic wall.

Following it upward, the sigmoid colon will be found to be completely covered by peri[illegible]neum, a mesocolon attaching the gut to the abdominal wall. A little higher up in the median line [illegible]e peritoneum passes forward, to enclose the small intestine, and, returning to the spinal column, [illegible]rms the mesentery (fig. 922). It now passes over the third part of the duodenum to the

FIG. 923.—REFLECTIONS OF THE PERITONEUM ON THE POSTERIOR ABDOMINAL WALL. (From Rauber-Kopsch, modified.)



pancreas, from which point it again passes forward to form the lower layer of the transverse mesocolon. It invests the transverse colon below and partly in front, and then leaves it to pass downward, forming the posterior layer of the great omentum. Then it returns and forms the anterior layer of the great omentum. Between the colon and stomach it forms the anterior layer of the gastrocolic ligament. On reaching the greater curvature of the stomach it goes over the anterior surface, and at the upper border (lesser curvature) forms the anterior layer of the lesser omentum, which extends between the stomach and the liver. It next invests the inferior surface of the liver in front of the porta hepatis (transverse fissure), and, turning over the anterior border of the liver, covers its upper surface. At the posterior part of the upper surface it leaves the liver and goes to the diaphragm, forming the anterior layer of the coronary

ligament. It covers the anterior part of the dome of the diaphragm, and, once more reaching the anterior abdominal wall, can be followed to the umbilicus, where the description began. This completes the boundary of the greater sac. On reference to the diagram (fig. 922) the student might be led to suppose that the two sacs are quite separate. This, of course, is not the case, since they communicate through the epiploic foramen (foramen of Winslow), as shown in the transverse section (fig. 921).

The peritoneum has been traced in this sagittal section only so far as it concerns the greater sac. It now remains to follow upon the same section (fig. 922) such part of the membrane as forms the **lesser sac** [bursa omentalis]. The peritoneum here will be seen to cover the posterior surface of the stomach; thence from the lesser curvature it runs upward to the liver, forming the posterior layer of the lesser omentum. It reaches the liver behind the porta hepatis, and covers the posterior surface of the caudate lobe. It is now reflected onto the diaphragm, forming the posterior layer of the coronary ligament. This portion of the bursa behind the liver is the *recessus superior*. The peritoneum now goes downward over the posterior part of the diaphragm to the vertebral column, separated from the latter by the great vessels. It passes over the anterior border of the pancreas, and then extends forward, to form the upper layer of the transverse mesocolon. It then covers the upper aspect of the transverse colon, and, descending, forms the inner layers of the great omentum. (The inner layers of the great omentum are usually fused in the adult, however, thus obliterating this portion of the lesser sac.) It then ascends, and, arriving at the greater curvature of the stomach, passes onto its posterior wall where the description began. The general relations of the greater and the lesser sac are also evident in fig. 923 showing the lines along which the parietal peritoneum is reflected from the posterior abdominal wall as the visceral peritoneum, forming the various mesenteries and covering the various abdominal organs.

The precise manner in which certain organs—such as the liver, the cecum, the duodenum, and the kidneys—are invested by peritoneum is described in the accounts of those viscera. To such accounts the reader is referred for a description of the many 'ligaments' (such as those of the bladder and liver) which are formed by the peritoneum.

The **bursa omentalis** (lesser sac) has already been described during development and as it appears in transverse and midsagittal sections of the adult (figs. 920, 921, 922). The general relations of the bursa are also well shown in figures 923 and 933.

The portion of the bursa behind the lesser omentum, adjacent to the epiploic foramen, is the *vestibulum bursæ omentalis*. From the vestibulum, the *recessus superior* extends upward behind the caudate lobe of the liver. A slight fold, the *plica gastropancreatica*, crosses the posterior wall below the recessus superior. The lower portion of the bursa is termed the *recessus inferior*, and the left extremity forms the *recessus lienalis*.

The **lesser omentum** [omentum minus] consists of a double layer of peritoneum extending between the stomach and the liver (figs. 922, 924, 933). If the two anterior layers of the great omentum are traced upward, they are seen to enclose the stomach, and then join together again at the lesser curvature to form the lesser omentum (fig. 922.) It is connected *above* with the liver at the porta hepatis (transverse fissure) and the fissure for the ductus venosus; ***below***, with the lesser curvature of the stomach and the first part of the duodenum; the *left* extremity joins the esophagus; the *right* border is free, forming the anterior boundary of the epiploic foramen (see fig. 924).

The lesser omentum is divided into two parts. The portion of the lesser omentum connecting the lesser curvature of the stomach with the fissure of the ductus venosus is the *gastrohepatic ligament* [lig. hepatogastricum]. The portion connecting the portal fissure of the liver with the first part of the duodenum, and enclosing the root-structures of the liver, is called the *hepatoduodenal ligament* [lig. hepatoduodenale]. Within this portion, near the right free border, are the root-structures of the liver; the bile-ducts on the right, the hepatic artery on the left, and the portal vein behind them (figs. 921, 933).

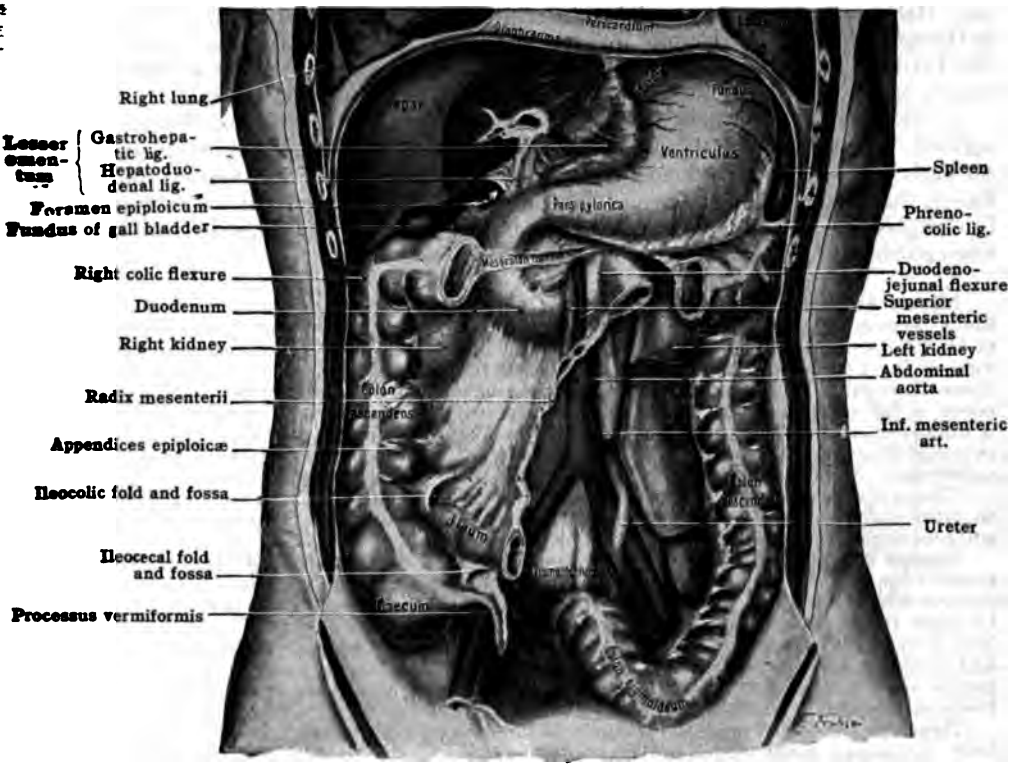
The great omentum.—As is evident from its development (figs. 919, 922), the great omentum [omentum majus] is formed of four layers of peritoneum, though usually this is quite impossible to demonstrate in an adult, the inner layers having become adherent. The great omentum acts as an apron (fig. 917), protecting the intestines and providing them with a heat-economizing covering of fat. It is nearly quadrilateral in shape, and is variable in extent. In fig. 922 the great omentum is shown to be connected with the greater curvature of the stomach, on the one hand, and the transverse colon, on the other. Originally it extended backward above the transverse colon and mesocolon to the posterior abdominal wall. The line along which it fuses with the transverse colon and mesocolon during development is shown in fig. 922. Superiorly it forms the gastrocolic and is continuous with the gastrolienal, and (on the left) with the phrenocolic ligaments (fig. 924).

Mr. Lockwood has made some investigations on the lengths of the transverse mesocolon and great omentum in thirty-three cases. In twenty, under the age of forty-five, only one subject had a great omentum long enough to be drawn beyond the pubic tubercle; in five, the omentum reached as far as the pubes. In the cases beyond forty-five years it was the exception rather than the rule to find an omentum which could not be pulled beyond the lower limits of the peritoneal cavity.

The **gastrosplenic ligament** [lig. gastrolienale] connects the left portion of the stomach with the spleen, continuing the layers of peritoneum which enclose the stomach (fig. 921). It is continuous below with the great omentum.

The **gastrocolic ligament** [lig. gastrocolicum] is that portion of the great omentum extending from the greater curvature of the stomach to the transverse colon. Superiorly it is continuous with the gastrosplenic ligament, and on the left it terminates in the phrenocolic ligament (figs. 922, 924).

FIG. 924.—ABDOMINAL VISCERA, ANTERIOR VIEW, AFTER REMOVAL OF A PART OF THE LIVER AND INTESTINES. (Rauber-Kopsch.)



The gastrophrenic and phrenocolic ligaments.—As the peritoneum passes from the diaphragm to the stomach it forms a small fold just to the left of the esophagus. This is the gastrophrenic ligament. A strong fold of the membrane also extends from the diaphragm (opposite the tenth and eleventh ribs) to the left colic (splenic) flexure, and is known as the phrenocolic (costocolic) ligament [lig. phrenicocolicum]. (See figs. 923, 924.)

Reflections of peritoneum.—The reflections of the peritoneum upon the posterior abdominal walls are well shown in fig. 923. As previously explained under 'general morphogenesis' (p. 1173), they represent chiefly transposed attachments of the primitive dorsal mesentery. The *coronary ligament* (with enclosed (bare area') represents a persistent portion of the primitive intimate relation between the liver and diaphragm (septum transversum). From the coronary ligament, the *falciform ligament* extends forward and downward along the anterior abdominal wall to the umbilicus, representing a portion of the primitive ventral mesentery (figs. 918, 923).

Upon the lower part of the anterior abdominal wall appear certain peritoneal folds of variable size (fig. 923). In the midline, the *plica umbilicalis media*

extends from the umbilicus to the apex of the bladder, and encloses the urachus (median umbilical ligament), a fibrous remnant of the embryonic allantoic stalk. Lateral to this median fold there appears on each side the *plica umbilicalis lateralis*, enclosing a fibrous cord (lateral umbilical ligament) representing the obliterated umbilical artery of prenatal life. Still more laterally on each side is a small inconstant fold, the *plica epigastrica*, enclosing the inferior epigastric vessels.

Corresponding to these peritoneal folds, three peritoneal fossæ appear on each side in the lower part of the abdominal wall. Between the median and the lateral umbilical plica is the *fovea supravesicalis*. Between the lateral umbilical and the epigastric plica is the *fovea inguinalis medialis*; while just lateral to the epigastric plica is the *fovea inguinalis lateralis*. The lateral inguinal fovea corresponds to the abdominal inguinal ring. For the relations of these peritoneal fossæ to hernia, see section XIV, p. 1397.

Within the pelvis, the peritoneal floor presents on each side two or three distinct transverse folds, forming corresponding fossæ. The most anterior is a somewhat variable fold, the *transverse vesical fold* [plica vesicalis transversa] (fig. 1041) extending from the bladder laterally to the pelvic wall. Behind this is the *ureteral fold* in the male, or the *broad ligament* in the female. Posterior to the bladder is the *sacrogenital fold* in the male (enclosing a part of the seminal vesicle and ductus deferens), and the *sacrouterine* fold in the female.

Corresponding to these folds, three pairs of pelvic peritoneal fossæ are described. Beside the bladder, and anterior to the ureteral fold (or broad ligament) on each side, is the *paravesical fossa* crossed by the transverse vesical fold. Between the ureteral fold (or broad ligament) and the sacrogenital (or sacrouterine) fold is the *paragenital fossa*, communicating with that of the opposite side through the *excavatio rectovesicalis* (rectouterine).

Minute anatomy.—The peritoneum, like all serous membranes, consists of two layers: a lining layer composed of simple squamous epithelium (mesothelium), and an underlying layer of fibrous connective tissue. The latter is highly elastic, and denser in the parietal than in the visceral layer. It often contains fat. In mesenteries and similar structures, the connective tissue is usually very scanty, except surrounding the vessels and nerves. Ruptures often occur in the omenta, which thus become fenestrated in structure. The visceral peritoneum is usually closely attached to the organs for which it forms the outer serous tunic, but the parietal peritoneum is often loosely attached to the adjacent wall by a fatty subserous layer [tela subserosa]. Smooth muscle occurs frequently in the various peritoneal folds.

The peritoneal cavity contains normally a very slight amount of watery fluid, which serves to lubricate the smooth peritoneal surface and thus to eliminate friction between adjacent surfaces during the movements of the alimentary canal.

Vessels and nerves.—The peritoneum is in general somewhat sparsely supplied with *blood-vessels* from various adjacent trunks. *Lymph-vessels* also occur, but they probably do not connect directly with the peritoneal cavity by stomata (as is found in the frog and as claimed by some to occur in man). They communicate with the lymphatics of neighboring regions. The *nerves* are also comparatively scarce. They are partly of sympathetic origin (vasomotor), and partly sensory nerves from the intercostal (7th to 12th) and lumbar nerves. The sensory nerves are more frequent in the parietal peritoneum and end in the connective tissue, either freely or in special end-organs (varying from simple end-bulbs to Pacinian corpuscles).

Development.—The principal features in the development of the peritoneum have already been mentioned in the section on DEVELOPMENTAL ANATOMY (p. 53) and in the remarks on the general morphogenesis of the peritoneum (p. 1172). Further details will be included later under the development of the intestine, etc.

Variations.—Variations in the form and relations of the peritoneum are exceedingly common, and are frequently of developmental origin. Variations in the form and relations of the various abdominal organs necessarily involve corresponding modifications in the peritoneum. The diaphragm may be incompletely formed, leaving the peritoneal cavity in communication with the pleural, or more rarely the pericardial cavity. The primitive dorsal mesentery of the intestine [mesenterium commune] may rarely persist unmodified, or the various secondary changes may be inhibited at any stage. Thus the stomach or the intestinal loop may fail, either wholly or partly, to undergo their characteristic rotations. The adhesions of the various mesenteries may be incomplete, or they may be more extensive than usual. For example, the sigmoid mesocolon may be more or less completely obliterated by adhesion, and numerous unusual peritoneal pockets or ligamentous bands may be formed in this way in various localities. Variations thus due to extensions of the normal developmental process are sometimes difficult to distinguish from pathological adhesions caused by peritonitis.

Comparative.—As previously mentioned, the cœlom or primitive body-cavity in vertebrates extends throughout the trunk region. In the cyclostomata, this primitive relation persists, the pericardial cavity remaining in communication with the general body-cavity. In all higher forms, however, the pericardial cavity becomes entirely separated. In amphibia the lungs lie in the general (pleuroperitoneal) body-cavity; in the reptiles and birds, they are partially separated; but a complete separation of the pleural cavities with the formation of the definite diaphragm occurs generally only in mammals.

ormation in the peritoneal cavity of a complete dorsal mesentery, and an incomplete
ıesentery (in the hepatic region) is typical for all classes of vertebrates. Slight modi-
in the form of the mesenteries depend chiefly upon the different degrees of complexity
:velopment of the various parts of the intestinal tract. The marked changes asso-
ith extensive secondary adhesions of the primitive peritoneal structures are found
›ng the higher mammalia, especially in man.

THE STOMACH

stomach [ventriculus; gaster] is a dilation of the alimentary canal suc-
the esophagus. In the stomach the food is mixed with the gastric juice
luced to a viscid, pulpy liquid, the chyme [chymus], which undergoes a
amount of digestion and absorption before passing into the duodenum.
stomach (figs. 924, 929) is a somewhat J-shaped sac located in the upper
: of the abdominal cavity. It presents a *body* [corpus ventriculi], with

25.—DIAGRAM OF THE PARTS OF THE
ɔMACH, ACCORDING TO FORSSELL.

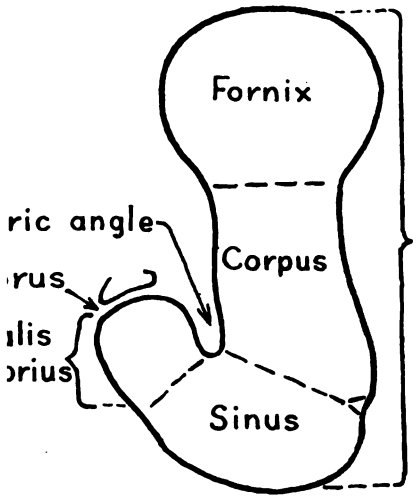


FIG. 926.—CHANGES IN THE FORM OF THE STOMACH. (Forssell.) Outlines as shown by the Röntgen-rays during upright posture after ingestion of 50, 200 and 400 cc. of Bi-meal. Gb, gas bubble; U, umbilicus; Im, infracostal margin.

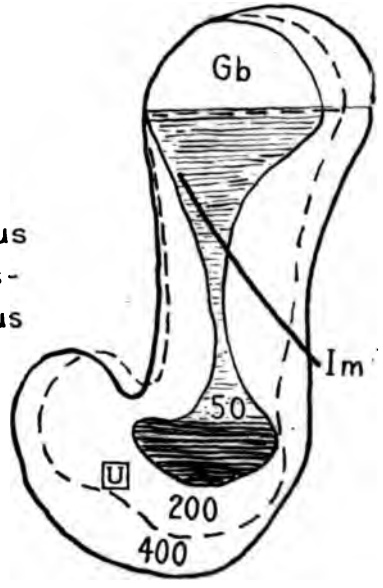


·ged upper end or *fundus*, on the right side of which is the *cardia*, the aper-
nmunicating with the esophagus. The body of the stomach is extremely
: in form, as will be explained later, but is in general divisible into a more
:d upper two-thirds, the *cardiac portion* [pars cardiaca], which is nearly
, and a more constricted lower third, the *pyloric portion* [pars pylorica],
urves toward the right. The junction of the cardiac and pyloric portions
he *gastric angle*. The pyloric portion presents a variable dilation, the
pylori, succeeded by a short constricted *pyloric canal* (Jonnesco) (fig.
At the lower end of this canal the *pylorus* forms the aperture leading into
denum, and contains a thick sphincter derived from the circular fibers of
scular layer. The stomach has two borders and two surfaces. The
border forms the *lesser curvature* [curvatura ventriculi minor], which is
: (except near the pylorus) and gives attachment to the lesser omentum.
teral (or lower) border forms the *greater curvautre* [curvatura ventriculi
which is convex, and gives attachment to the great omentum. The
res separate the *anterior surface* [paries anterior], which faces forward and
, from the *posterior surface* [paries posterior], which is placed backward
vnward.

result of careful and extensive researches upon the anatomy of the stomach, with
eference to the form of the living stomach shown by the Röntgen-rays, Forssell divides

the organ into *saccus digestorius* and *canalis egestorius* (fig. 925). The saccus is divided fornix, corpus and sinus. The sinus corresponds roughly to the antrum pylori above mentio The canalis egestorius is the constricted pyloric canal, whose primary function is to reg the passage of food from the digestive sac.

Form.—The form of the stomach varies especially with the amount of tents (fig. 926). When nearly empty it presents throughout a narrow, tul form, excepting in the region of the fundus (fornix). This region, which con the gas-bubble, remains somewhat distended even when the remainder o stomach is empty and contracted. When food is introduced, it fills succes the various portions of the stomach as shown in fig. 926, the antrum (sinus) filled first and the pyloric canal usually last.

FIG. 927.—RADIOGRAPH OF STOMACH, PARTLY FILLED; BODY IN UPRIGHT POSTU This form is most pronounced in individuals of hyposthenic type. Gas-bubble in (fornix) region. Duodenal antrum visible just above the pylorus in the midline. (Fro by Dr. R. W. Mills, Washington University Medical School.)

The J-shape is typical for the upright posture; but in the dorsal position the lower curvature of the stomach becomes elevated and r stricted, the fundus (fornix) more distended and displaced to the left, so tends to assume the 'cow-horn' form (fig. 928A), with the axis of the car tion more obliquely placed.

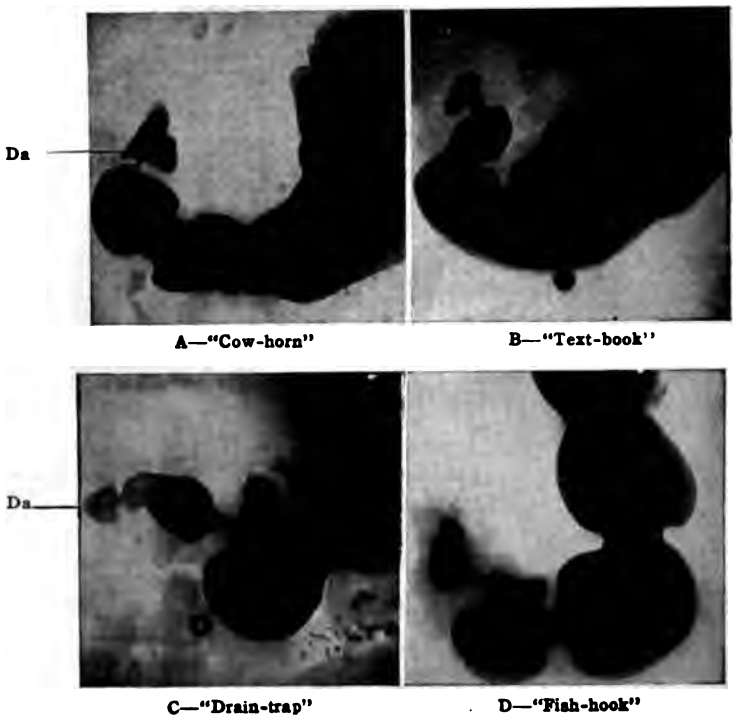
Dimensions.—The dimensions of the stomach are subject to great variation. Th the lesser curvature averages about 10 cm. (7.5 cm. to 15 cm.), and that of the greater is three or four times as great. The *diameter* varies exceedingly according to the contents. When nearly empty, it presents (excepting the fundus region) a narro form, with a diameter of about 4 or 5 cm. The diameter of the pylorus, which is the point in the alimentary canal below the esophagus, when constricted is only about 1.5 distensible, however, as hard bodies with diameters of 2 cm. or more may readily pas The average *capacity* of the stomach is about 1 liter, being subject to extreme variations. In the newborn, it averages about 30 cc. (see p. 44). The average we adult stomach is about 135 gm.

Position and relations of the stomach.—The position and relation stomach, like its form and structure, are subject to many variations in

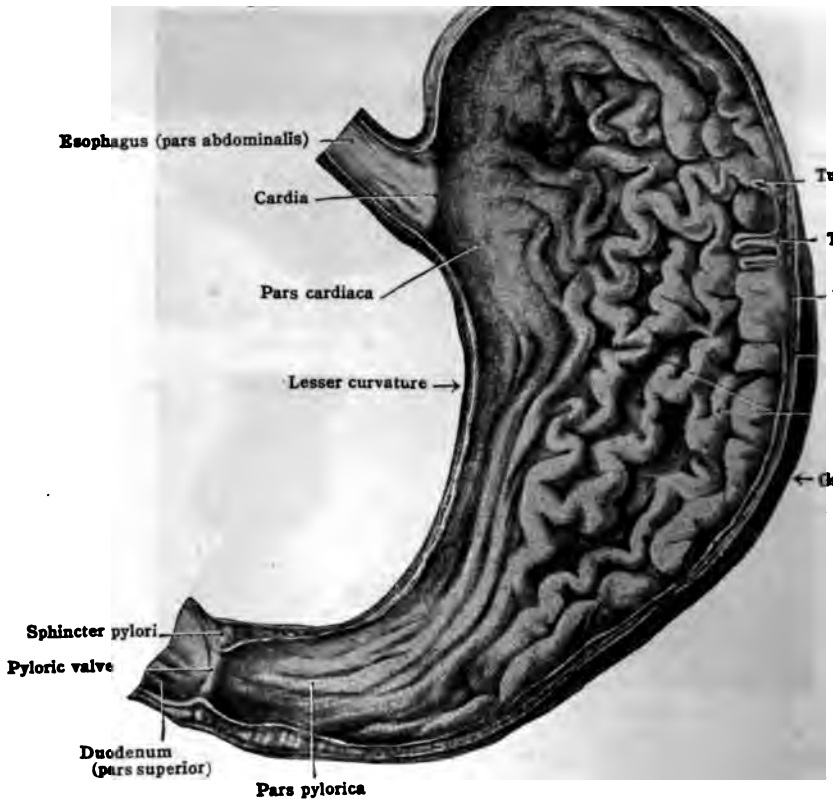
viduals, and in the same individual according to changes in physiological dition, distention, posture, etc. It is therefore difficult to give a concise and urate description. The stomach is fixed and supported chiefly by (1) the achment at the cardia; (2) the attachment at the pylorus; (3) the support of adjacent viscera, especially (in the upright posture) by the transverse meso- on and adjacent intestines, which in turn are supported by the musculature of abdominal wall.

Topography.—In *surface relation* (figs. 917, 926, 1095), the stomach lies within left hypochondriac and the epigastric regions. Often, however, especially hen distended, it extends into the umbilical and even the right hypochondriac egion. When empty, it usually lies almost entirely in the left half of the body,

FIG. 928.—DIFFERENT FORMS OF THE STOMACH AS SHOWN BY THE RŒNTGEN RAYS. (Cole.) Fundus not represented. DA, Duodenal antrum. Position of umbilicus shown in B and C.



with the pylorus near the midsagittal plane. When distended, the stomach is lengthened and the pylorus may be displaced 5 cm. or more to the right and downward. In distention, the stomach expands in all directions (fig. 926); it changes in form, as above mentioned, but does not appear to rotate as is sometimes stated. The position of the stomach, especially when distended, also varies appreciably according to the *posture* of the body. It sags downward when the body is in the upright position, so the lowest part may normally reach considerably below the umbilicus (fig. 927). The stomach is also displaced to the right or left when the body is placed on the corresponding side. The *cardia*, which is the most fixed point, lies on the left side of the 10th or 11th thoracic vertebra, and corresponds to a surface point behind the left 7th costal cartilage about 2.5 cm. from its sternal end. The *pylorus* usually lies opposite the right side of the 1st. lumbar vertebra, about midway between the xiphoid cartilage and umbilicus, (in Addison's 'transpyloric line,') when the body is recumbent; but descends to the 2d or 3d vertebra (rarely lower) in upright posture. The *fundus* corresponds to the left dome of the diaphragm (which separates it from the lung and heart), opposite the sixth sternocostal junction. The fundus necessarily rises and falls with respiratory movements of the diaphragm, the excursion ordinarily being from 2 to 6 cm. The variations in the position of the stomach according to types of physique, and the changes during peristalsis, are mentioned later.



Peritoneal relations.—The stomach is covered by peritoneum i
extent, except immediately along the curvatures and upon a small
space behind the cardiac orifice, where the viscus lies in direct c
the diaphragm, and possibly with the upper part of the left supra

3. 930.—Longitudinal Section of the Pyloric Portion of the Stomach. (Cunningham, Trans. Royal Soc. Edinb., vol. 45.)

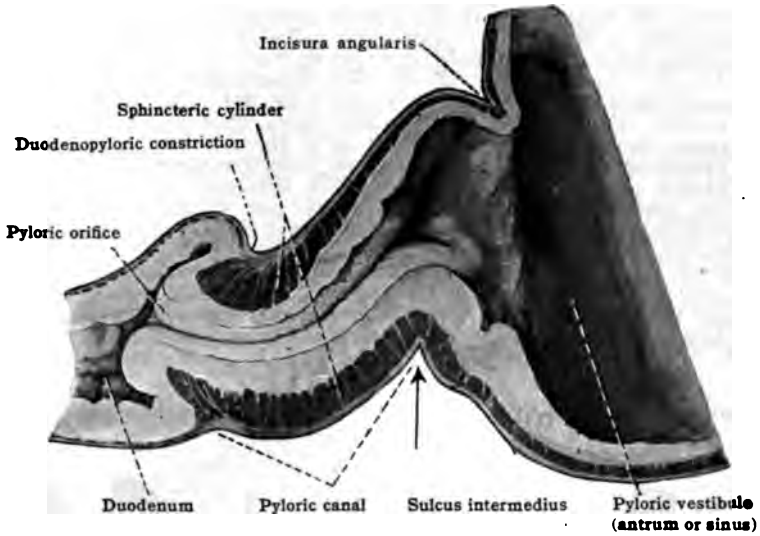


Fig. 931.—Diagrammatic Section of the Stomach Wall Showing (*A*.) The Blood sels, (*B*) the Tunics, and (*C*) the Lymphatics. *M*, Mucosa. M_1, Muscularis mucosæ. *S*, bmucosa. *I*, Circular, and *O*, longitudinal muscle-layer. (Szymonowicz, after Mall.)

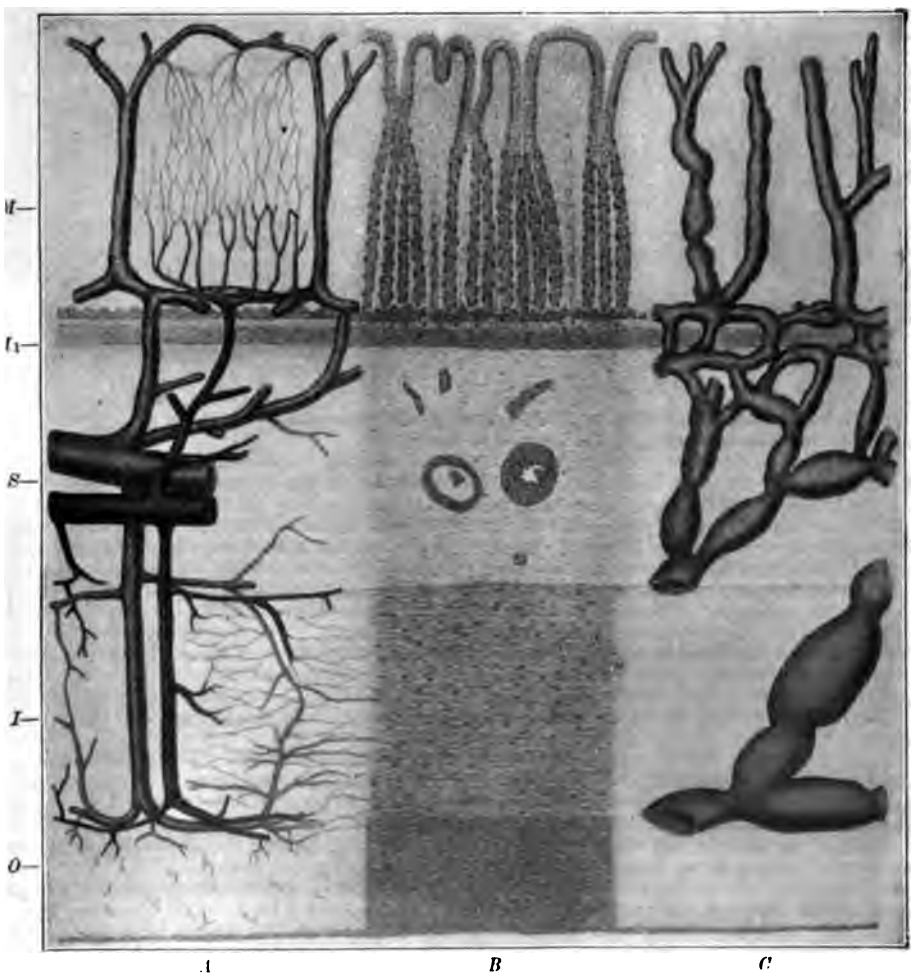
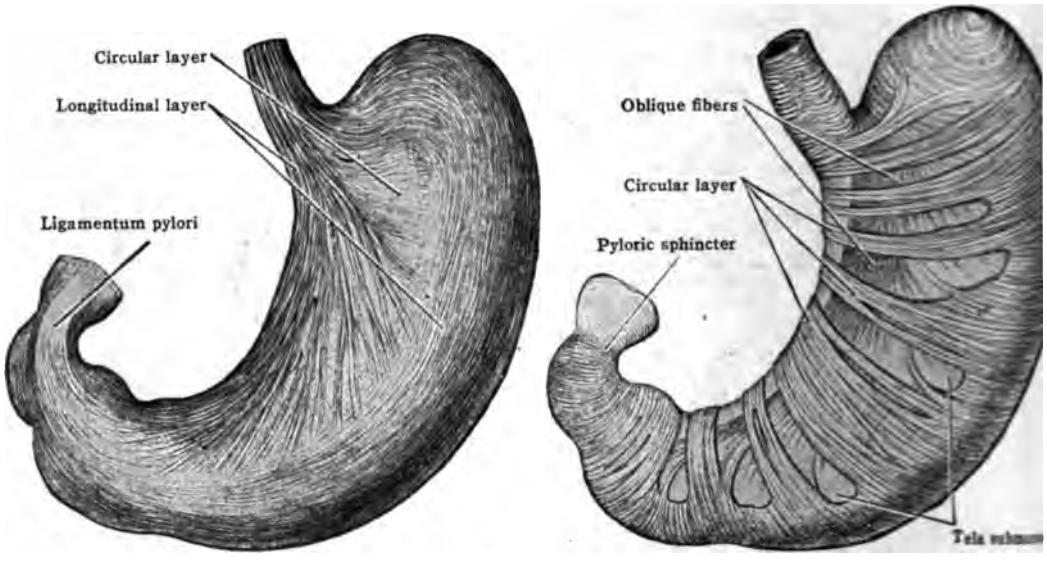


from cardia to pylorus. Upon closer examination the inner surface of the mucosa presents a somewhat warty ('mammilated') appearance, due to numerous small elevated areas (*areæ gastricæ*), varying from 1 to 6 mm. in diameter. When examined with a lens, it is seen that each area is beset with numerous small *pits* [foveolæ gastricæ], separated by partitions which sometimes (especially in the pyloric region) bear villus-like prolongations [plicæ villosæ]. The average number of foveolæ is estimated at 89 per sq. mm., or nearly 7 millions for the entire stomach (Toldt). Into each pit or foveola open 3 to 5 gastric glands.

The relations of the mucosa in section are shown in fig. 931. The thickness of the mucosa varies, being greatest (about 2 mm.) in the pyloric region, decreasing to less than .5 mm. in the cardiac region (Kölliker). The *lamina propria* is crowded with *glands*, of which three varieties are distinguished. The *cardiac* glands are tubuloracemose (chiefly mucous) glands occupying a narrow zone a few millimeters in width adjacent to the cardiac orifice. The *fundic* glands [gl. gastricæ propriæ] occupy the greater part of the stomach, and are simple (partly branched) tubular glands (fig. 931). The *pyloric* glands [gl. pyloricæ] are branched tubular glands occupying the pyloric region.

The interstitial tissue of the lamina propria contains diffuse lymphoid tissue and often small *lymph nodules*, especially in the pyloric region. The *muscularis mucosæ* is a thin sheet of smooth muscle lying just below the fundus of the glands and is composed of an inner circular and an outer longitudinal layer.

FIG. 932.—DISSECTIONS SHOWING THE MUSCULAR LAYERS OF THE STOMACH. (From Toldt's Atlas.)



The *tela submucosa* (fig. 931) is a very loose areolar, vascular layer which permits the wrinkling of the mucosa according to the degree of distention.

The *tunica muscularis* contains three layers of smooth muscle (fig. 932). The outer or *longitudinal* layer [stratum longitudinale] is thickest along the lesser curvature, and is continuous with the longitudinal fibers of the esophagus and the duodenum. On the anterior and posterior walls of the antrum pylori, the longitudinal fibers form thickened bands, the *ligamenta pylori*. The middle or *circular* layer [stratum circulare] is continuous with the circular fibers of esophagus and duodenum and surrounds the entire stomach. It is especially thickened in the region of the pyloric canal, at the lower end of which it forms a thickened ring-like band, the pyloric *sphincter* [m. sphincter pylori]. The inner or *oblique* layer [fibræ obliquæ] is composed of fibers continuous with the deepest circular fibers of the esophagus. They form an incomplete layer which encircles the fundus and passes obliquely downward around the body of the stomach toward the greater curvature. Forssell has shown the fundamental importance of the arrangement of the musculature in determining the form of the stomach under various conditions.

The external *tunica serosa* is formed by the peritoneum, and has the smooth shiny appearance and the structure typical for a serous membrane.

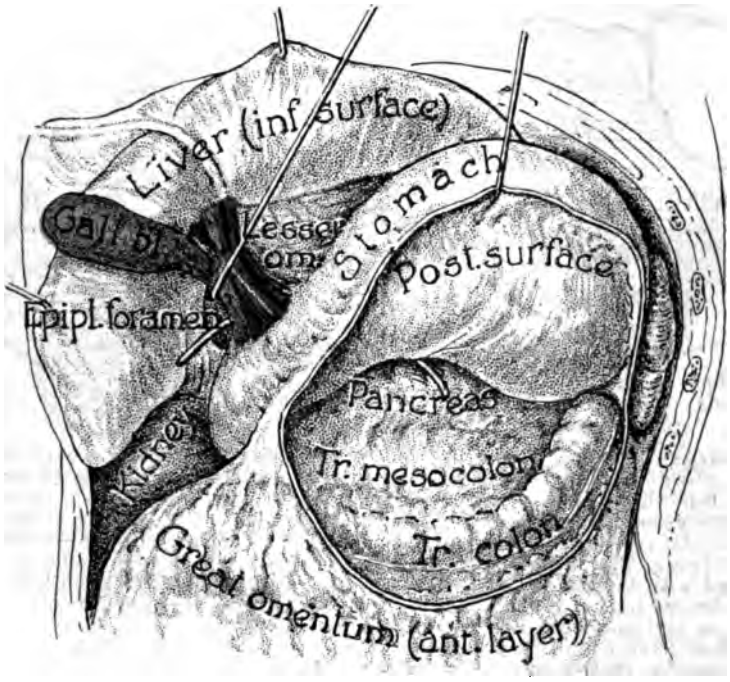
Blood-vessels.—The stomach receives its blood-supply from many branches. From the coeliac axis there is the left gastric artery, which runs along the lesser curve from left to right anastomosing with the right gastric branch of the hepatic. Along the greater curvature run the right and left gastroepiploic arteries, anastomosing at the middle of the border, the left being a branch of the splenic, the right a branch of the hepatic, through the gastroduodenal artery. The stomach also receives branches from the splenic (vasa brevia) at the fundus. The vascular arches along the curvatures of the stomach are comparable to those in the intestinal mesentery (Mall). The blood of the stomach is returned into the portal vein. The coronary vein and pyloric vein open separately into the portal vein; the right gastroepiploic vein opens into the superior mesenteric, the left into the splenic. The arrangement and distribution of the blood-

vessels within the stomach wall are illustrated in fig. 931. The rich capillary plexus in the mucosa supplies the glands and also serves for absorption.

Lymphatics.—There is a set of nodes lying along the lesser curvature and the pyloric portion of the greater curvature, and others at the pyloric and cardiac ends. These are entered by lymphatic vessels which, beginning in the mucous membrane (fig. 931), accompany all the gastric veins, but chiefly those of the lesser curvature. Vessels also accompany the left gastroepiploic veins to terminate in the splenic nodes (see fig. 617). On its way to the cisterna chyli, the gastric lymph passes through groups of nodes [lymphoglandulæ pancreaticolienales] situated above and behind the head and neck of the pancreas.

Nerves.—The nerves of the stomach are derived in part from the vagi (which form the motor fibers of the stomach), the right vagus descending on the posterior wall, and the left on the anterior wall. The stomach also receives sympathetic branches from the celiac plexus, following the arteries. Small ganglia occur along both vagus and sympathetic branches (Remak). The nerves join the gangliated plexuses, myenteric and submucous, in the wall of the stomach, from which branches are distributed to the muscularis and the mucosa as for the intestine in general.

FIG. 933.—GASTRIC REGION. Liver elevated and omental bursa opened by section along the gastrocolic ligament. Probe passed through the epiploic foramen. (After Hertzler.)



Development.—For development of the stomach, see DEVELOPMENTAL ANATOMY, p. 42; also *general morphogenesis*, p. 1173.

Glands.—According to Johnson, in an embryo of 16 mm., the lining epithelium shows the primitive foveolæ as pit-like depressions which become elongated, forming irregular anastomosing grooves, separated by villus-like projections. The pits multiply and deepen, and from their bottoms the gastric glands bud off (at 120 mm.).

Variations.—The great variability of the stomach in form, position and relations has already been repeatedly emphasized. These variations, which depend chiefly upon the factors already mentioned, have been observed both in properly fixed dead bodies and in the living body by means of the Rœntgen-rays.

Physique.—As has recently been emphasized by Mills, visceral form and topography in general, while subject to marked individual variations, are often closely correlated with certain types of general physique. The extremes are the hypersthenic type, with broad thorax and capacious upper abdomen, and the asthenic slender type, with narrow thorax and small upper abdomen. In the hypersthenic type, the stomach ('cow-horn' type) and transverse colon are placed high, scarcely reaching the umbilical zone; while in the asthenic type, both sag low, toward the pelvic region, approaching the condition known as *gastroptosis* (visceroptosis). Between these two extremes are the sthenic and hyposthenic types, in which the conditions are intermediate in character.

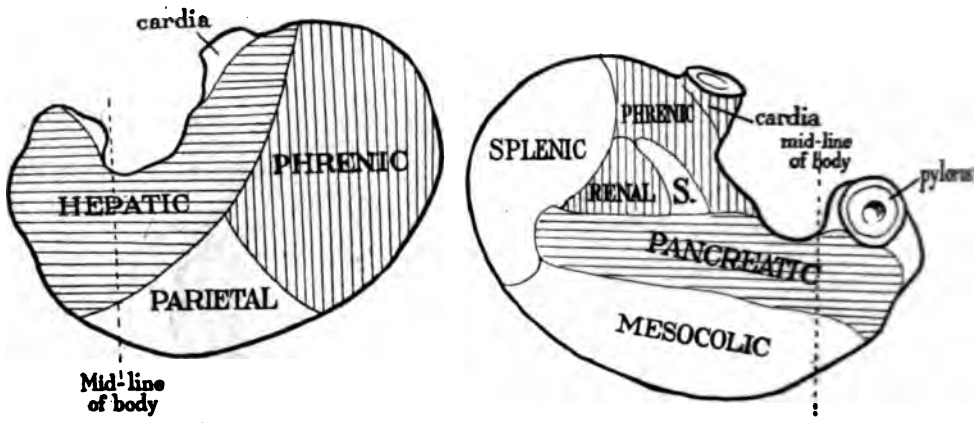
Peristalsis.—It would appear that many of the variations in the form of the stomach that have been described are merely various phases in the series of changes undergone by the stomach during the normal process of physiological digestion. Observations by various investigators upon the living stomach of man and lower animals (especially the radiographic study of the cat by Cannon) have shown that the pyloric portion during digestion usually presents

distinct peristaltic contractions passing pylorusward. Peristaltic contractions may also be observed to begin in the cardiac portion, although they are usually most distinct in the pyloric portion (fig. 928). In addition to the peristaltic waves, stationary constrictions may appear at various points, but all of these are transient in character (Forssell). The constrictions most frequently observed form the *incisura angularis* on the lesser curvature near the gastric angle and the *sulcus intermedius* on the greater curvature between the sinus (antrum) and the pyloric canal (figs. 925, 927, 928, 930).

In the earlier stages of gastric digestion the pylorus usually remains closed, but after a variable time it relaxes slightly (lumen about 3 mm. in diameter) at intervals, allowing the chyme to be spurted into the duodenum. This forms the 'duodenal antrum' seen with the *X*-rays (figs. 927, 928).

Thus the various constrictions often found in the formalin-hardened stomachs, and the pyloric antrum, appear to be merely transient phases of the digestive process. The 'hour-glass' stomach (fig. 927) is in most cases to be explained in this way; in others, however, the constriction is pathological and permanent. Various forms of abnormal lobulations and dilations also rarely occur.

FIG. 934.—DIAGRAM OF THE CONTACT AREAS OF THE STOMACH, ANTERIOR AND POSTERIOR VIEWS.



Comparative.—The primitive stomach is perhaps merely a receptacle for food, true digestive glands being absent in many of the fishes. The vertebrate stomach is a dilated sac of variable form, but is typically somewhat looped, with cardiac and pyloric segments. In *birds*, there is a peculiar arrangement, correlated with the absence of teeth. The stomach is divided into an anterior glandular *proventriculus*, and a posterior muscular *gizzard* with a horny lining serving to grind the food. The *mammalian* stomach is most variable in form and structure, which are correlated with the method and character of alimentation. The three kinds of glands, cardiac, fundic and pyloric, are typically present. In general, the stomach is larger and more complicated in herbivora than in carnivora. Instead of being a single sac, the stomach may be more or less divided into chambers. An incomplete division into cardiac and pyloric portions is so common that it may be considered typical. The most extreme specialization is found in the ruminants. In these the stomach has four chambers, the first two of which, however, are expansions of the esophagus.

THE SMALL INTESTINE

The **small intestine** [intestinum tenue] extends from the pylorus to the ileocecal orifice, and occupies most of the abdominal cavity below the liver and stomach. It is a cylindrical tube whose diameter decreases from about 4 cm. above to about 2.5 cm. at the lower end. Its *length*, when removed from the body and measured fresh, averages about 7 meters (23 ft.); but when formalin-hardened *in situ*, the length (which is probably nearer that during life) is only about 4 meters. The length does not seem to vary according to sex, height or weight in the adult.

The small intestine includes two main divisions, the ***duodenum*** and the *mesenteric small intestine*, the latter being further subdivided into ***jejunum*** and *ileum*.

THE DUODENUM

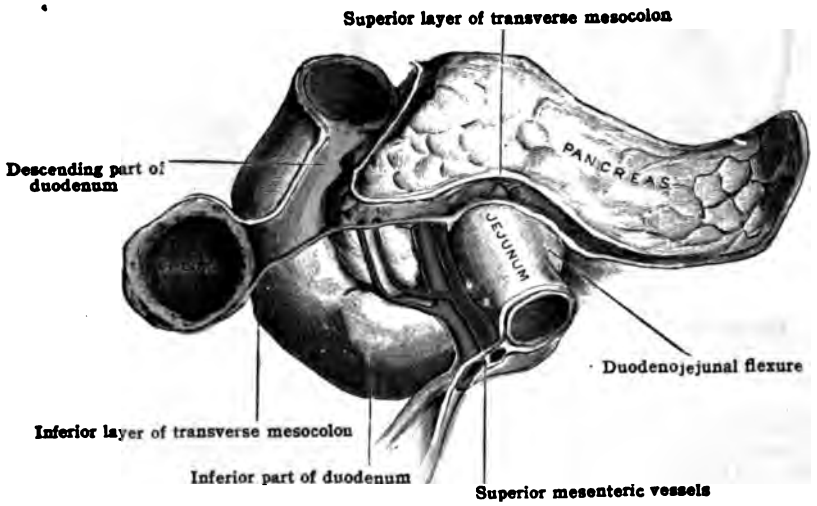
The **duodenum** is the first part of the small intestine, and is very definite in position and extent. It is firmly attached to the posterior abdominal wall, being almost entirely retroperitoneal. It is the widest part of the small intestine, the

average width being 4 cm. or more, and is also the shortest segment, being only about 25 cm. in length. In general, it is somewhat C-shaped, the concavity enclosing the head of the pancreas (figs. 935, 936).

Parts.—For convenience of description, the duodenum is divided into the following parts: (1) the *superior portion* [pars superior] which is short (5 cm. or less), leading from the pylorus and forming the *superior flexure* [flexura duodenalis superior]; (2) the *descending portion* [pars descendens], about 7 or 8 cm. in length, which receives the bile and pancreatic ducts and joins the inferior portion at the *inferior flexure* [flexura duodenalis inferior]; (3) the *inferior portion* [pars inferior], which is again subdivided into (a) *horizontal* portion [pars horizontalis], about 10 cm. long, which usually ascends slightly and passes gradually into (b) the *ascending portion* [pars ascendens], 2 or 3 cm. long, terminating in the *duodenojejunal flexure* [flexura duodenojejunalis].

Position and relations.—As shown in fig. 965, the duodenum usually lies chiefly in the lower part of the epigastric region, only the inferior (horizontal) portion extending into the umbilical region. All but the terminal (ascending) portion of the duodenum usually lies to the right of the midline.

FIG. 935.—THE DUODENUM AND PANCREAS, ANTERIOR VIEW.



The *superior* portion usually lies at the level of the first lumbar vertebra (or the disk below). It is covered anteriorly, and to a variable extent posteriorly, by a prolongation of the peritoneum from the corresponding surfaces of the stomach. It is somewhat freely movable. When the stomach is empty, it extends from the pylorus almost horizontally to the right and backward. As the stomach becomes distended, however, the pylorus is carried to the right and downward for a variable distance, and the position of the superior part of the duodenum is correspondingly altered.

Superiorly it is in contact with the liver (quadrate lobe) and the neck of the gall-bladder and forms the lower boundary of the epiploic foramen; *anteriorly*, with the liver and (often) the transverse colon; *inferiorly* and *posteriorly*, with the head of the pancreas below, and with the common bile-duct, hepatic vessels and portal vein above.

The second or *descending* portion of the duodenum extends along the right side of the first to the third lumbar vertebra. It is covered anterolaterally by peritoneum, excepting (usually) the area of contact with the transverse colon (fig. 935).

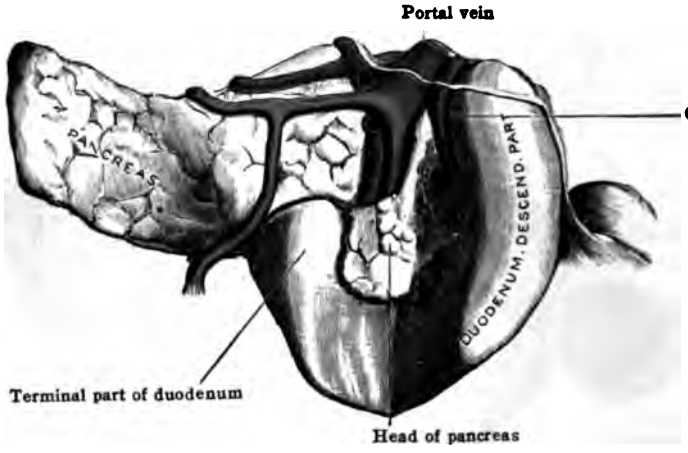
Posteriorly (fig. 965) it is in contact with the right kidney, ureter and renal vessels, and below with the psoas muscle. *Anteriorly* (fig. 924) it is crossed by the transverse colon (the layers of the transverse mesocolon usually separated by an area of direct contact); above the colon, it may be in contact with the gall-bladder, and below the colon with coils of small intestine. The *left or medial* aspect of the descending duodenum (figs. 935, 936) is in contact with the head of the pancreas, and some fibers from the muscular tunic are said to become intermingled with the pancreatic lobules. Somewhat posteriorly the common bile-duct descends between pancreas and duodenum, and enters the descending duodenum, in common with the pancreatic duct, about 10 cm. below the pylorus (fig. 964). The loop formed by the pancreaticoduodenal arteries also runs along the descending duodenum.

The third or *horizontal* portion of the duodenum usually crosses the body of the third lumbar vertebra, ascending slightly from the right to the left side (figs. 935, 936). It is covered anteriorly with peritoneum, excepting a small space where the superior mesenteric vessels enter the root of the mesentery.

Anteriorly it is further in contact with coils of small intestine; *superiorly*, with the head of the pancreas, and the inferior pancreaticoduodenal vessels; *posteriorly*, with the vena cava.

The terminal or *ascending* portion is covered anteriorly and laterally by peritoneum, and is in contact with coils of the ileum. To the *right* it is in relation with the head of the pancreas (processus uncinatus) and the superior mesenteric vessels; and *posteriorly* with the psoas muscle, aorta and left renal vessels. The *duodenojejunal flexure* usually lies opposite the second lumbar vertebra, and is in contact above with the inferior surface of the body of the pancreas, and the root of the transverse mesocolon.

FIG. 936.—THE DUODENUM AND PANCREAS, POSTERIOR VIEW.



The lower end of the duodenum is firmly fixed in its place by the *musculus suspensorius duodeni*, or *suspensory ligament of Treitz*. This name has been given to a fibromuscular band that contains, according to Treitz, smooth muscular fibers, and descends to the terminal part of the duodenum from the lumbar part of the diaphragm, passing to the left of the celiac artery and behind the pancreas. Lockwood points out that this band is continued on, after being inserted into the duodenum, between the layers of the mesentery. He suggests the name of the 'suspensory muscle of the duodenum and mesentery,' and says, 'together with the other constituents of the root of the mesentery, it forms a band of considerable strength, sufficient not only to support the weight of the intestines and mesentery, but also to resist the pressure of the descent of the diaphragm.'

In connection with this fourth portion of the duodenum, mention may be made of certain peritoneal folds and fossæ which are of some surgical interest by reason of their being associated with retroperitoneal hernia. Four such fossæ may be mentioned, namely, the superior and inferior duodenal fossæ, paraduodenal and the retroduodenal fossæ. On drawing the terminal portions of the duodenum to the right, two triangular folds of peritoneum, the superior and inferior duodenal folds, which extend from the wall of the duodenum to the posterior abdominal wall, may be observed (fig. 937). Each fold has a free edge. Beneath each fold is found a pouch of peritoneum, constituting the superior and inferior duodenal fossæ. The former, the smaller, opens downward and is present in about 50 per cent., while the latter opens upward and is present in about 75 per cent. of the subjects examined (Jonnesco). The paraduodenal fossa (fossa of Landzert) is not often found in the adult; when present, it is situated to the left of the last part of the duodenum, and is formed by a fold of peritoneum enclosing the inferior mesenteric vein. The retroduodenal fossa is a rare form extending from below upward behind the transverse portion of the duodenum.

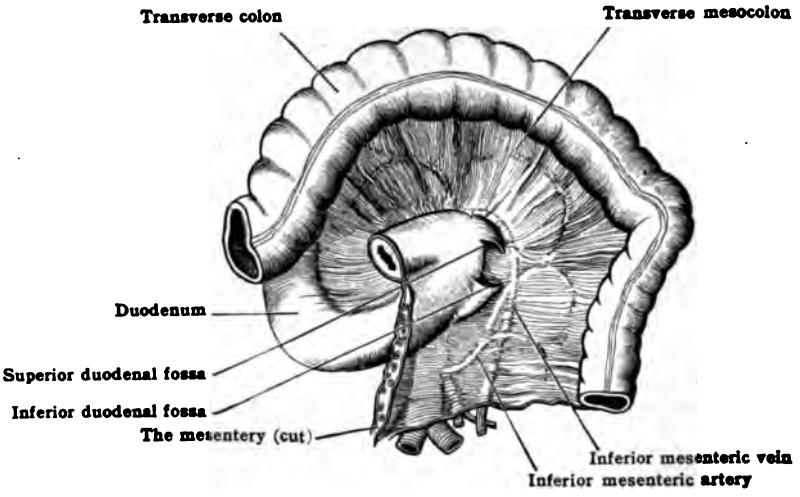
Interior of the duodenum.—The interior of the first part of the duodenum is smooth. The pylorus is often somewhat invaginated, much in the same way that the uterus projects into the vagina (fig. 930). On account of this arrangement (which renders the complete emptying of the cavity somewhat difficult) and also on account of the distensibility of this portion, it is frequently seen very distinctly in radiographic pictures as a 'cap' (antrum) at the pyloric end of the stomach during digestion (fig. 928). In the lower portions of the duodenum, transverse ridges or folds of the mucosa appear which are also apparent in radio-

graphs occasionally. On the medial wall of the descending portion, posteriorly, about half-way down, is a more or less distinct *longitudinal fold* [plica longitudinalis duodeni], toward the lower end of which is a small elevation, the bile papilla or *papilla major* [papilla duodeni], upon which open the common bile duct and the pancreatic duct, either separately or by a common aperture.

Above the papilla there is usually a prominent *hood-like fold* (valvula connivens), and below it a variable fold or *frenum* which forms a continuation of the plica longitudinalis. About 2 cm. (0.9 to 3.5 cm., Baldwin) above and in front of the bile papilla there is a second, smaller, rounded *papilla minor*, upon which the accessory pancreatic duct (of Santorini) ends.

The minute structure, vascular relations, development, variations, etc., of the duodenum will be considered later, with those of the small intestine as a whole.

FIG. 937.—DOUDENAL FOSSÆ AND FOLDS. Paraduodenal fossa is not shown. (After Cunningham.)



THE JEJUNUM AND ILEUM

The mesentric portion of the small intestine is divided into an upper portion, the *jejunum*, and a lower portion, the *ileum*. Although the character of the gut changes considerably from the upper end of the jejunum to the lower end of the ileum, the transition is gradual, and there is no definite line of demarcation. In general, the jejunum is somewhat wider, has thicker walls, is more vascular and has a more complicated mucosa. The lymphoid organs (Peyer's patches) are, however, characteristic of the ileum.

The **jejunum** begins at the duodenojejunal flexure. The first coil is variable in direction, being found (in order of frequency) as follows: (1) downward, forward and to the left; (2) directly forward and downward; (3) to the left, then downward; (4) forward and to the right (Harman). Some further details as to the position of the various succeeding coils are given later under the development of the intestine (figs. 942, 943). While there is considerable individual variation it is true in general that the coils of *jejunum* occupy the upper and left portion of the body cavity, while those of the *ileum* occupy the lower and right side, the lower portion lying in the pelvic cavity. The ileum finally passes upward over the pelvic brim to the right iliac fossa where it terminates in the ileocecal orifice.

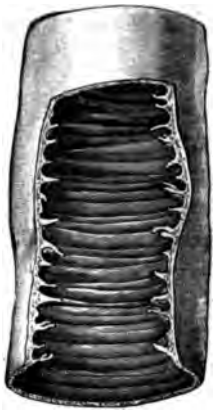
The **mesentery** [mesenterium] is a fan-shaped fold extending from the duodenojejunal flexure to the ileocecal junction. It is composed of a double layer of peritoneum which encloses and supports the jejunum and ileum and their vessels, connecting them with the abdominal wall. The *root* of the mesentery [radix mesenterii], or parietal attachment, is only about 15 cm. long, corresponding to a line extending from the duodenojejunal flexure obliquely downward and to the right, across the transverse duodenum, the great vessels and the vertebral column to the ileocecal junction (fig. 923).

The *visceral* attachment of the mesentery to the intestine, corresponding to the length of the jejunoileum, is nearly 7 meters long, and is thinner than at the root. The *width* of the

mesentery, measured from parietal to visceral attachment, varies somewhat in different parts of the canal, the average being 18 or 20 cm. (ranging from 15 to 22.5 cm.). It is narrow above (also at the lower end), but reaches its full width, about 30 cm., below its upper end. Between the two peritoneal layers of the mesentery is a third layer [lamina mesenterii propria] containing the superior mesenteric vessels (arteries, veins and lymphatics) with their branches and accompanying nerves, the small mesenteric lymph-nodes (50 to 100 in number), and a variable amount of fibroadipose connective tissue.

Minute anatomy.—The small intestine has the four typical layers—mucosa, submucosa, muscularis and serosa (fig. 941). They are, in general, somewhat similar in structure to those of the stomach (fig. 931), excepting the mucosa.

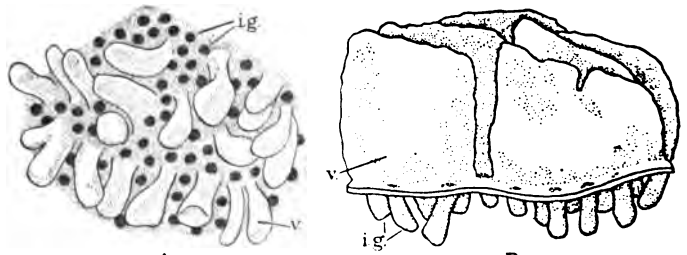
FIG. 938.—PORTION OF THE SMALL INTESTINE, LAID OPEN TO SHOW THE PLICÆ CIRCULARES. (Brinton.)



The **mucosa** is lined with a simple cylindrical epithelium, underneath which is a fibrous *lamina propria*, limited externally by a *muscularis mucosæ*, as in the stomach. The muscularis mucosæ sends slender muscular bundles upward into the villi. The inner surface of the mucosa (fig. 938) presents numerous coarse, closely set, transverse folds [*plicæ circulares*]. These are permenent, crescentic folds, involving both mucosa and submucosa, and usually extending one-half to two-thirds of the way around the lumen. They often branch and anastomose, sometimes forming circles or spirals. The largest exceed 5 cm. in length and 3 mm. in width. The plicæ circulares are absent from the first part of the duodenum, but become well marked in the descending portion. They are largest and best developed in the lower duodenum and upper half of the jejunum, below which they gradually become smaller (fig. 938) and disappear at the lower end of the ileum. The total number of plicæ in the adult is about 800 (Gundobin).

The digestive and absorptive surface of the small intestine is further greatly increased by multitudes of small processes, the *villi* (fig. 939), which give the mucosa a velvety appear-

FIG. 939.—*A*, SURFACE VIEW OF THE HARDENED MUCOSA OF THE SMALL INTESTINE. (After Kölliker.) *B*, SIDE VIEW OF A WAX RECONSTRUCTION OF THE EPITHELIUM IN THE HUMAN DUODENUM. (Huber.) *i.g.*, Intestinal gland. *v.*, Villus.

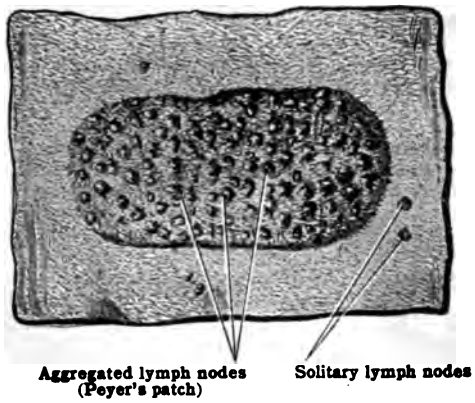


ance. They are largest (0.5 to 0.7 mm. in height) and most numerous in the duodenum and jejunum, where they are typically leaf-shaped, and gradually become smaller, scattered and conical in the ileum. The villi are much reduced in distention of the intestine, and may even be temporarily obliterated. Between the bases of the villi there open short, simple tubular glands—the crypts of Lieberkuehn [gl. intestinales]. In the duodenum there are found, in addition, the larger tubuloracemose glands of Brunner [gl. duodenales], which occupy the submucosa, and are especially numerous in the upper portion of the duodenum. They are purely mucous in character, according to Bensley.

Scattered over the whole of the mucous membrane of the small intestine are numerous small lymph-nodules, the larger of which extend into the submucosa; these are the so-called *solitary glands* [noduli lymphatici solitarii]. Aggregations of lymph-nodules, known as *Peyer's*

patches [noduli lymphatici aggregati], situated in the mucosa and submucosa, are found in the ileum especially toward the lower end (fig. 940). They are oval, from 1.2 to 7.5 cm. in length and about 1 to 2.5 cm. in breadth, and are placed in the long axis of the bowel along a line most remote from the mesentery. They are variable in number, the average being about 20 to 30.

FIG. 940.—SURFACE VIEW OF THE MUCOSA OF THE ILEUM, SHOWING AGGREGATED LYMPH-NODES (Peyer's Patch). (From Toldt's Atlas.)



The **submucosa** is in general a loose areolar layer containing vascular and sympathetic plexuses (fig. 941). The **muscularis** is composed of smooth muscle arranged in the two typical layers—a thinner, outer longitudinal and a thicker, inner circular— both of which become thinner toward the lower end of the ileum. The **serosa** is typical in structure, the squamous epithelial covering being absent in the retroperitoneal areas of the duodenum.

(Lewis and Stöhr.)

Blood-supply of the small intestine.—The small intestine receives its blood from the superior mesenteric artery and a branch coming indirectly from the hepatic, the superior pancreaticoduodenal. The superior mesenteric artery runs between the layers of the mesentery and gives off six or seven relatively large branches and a variable number of smaller branches. The first two or three of the larger branches divide into an ascending and a descending branch, which join above and below with the corresponding branches of the contiguous arteries, form-

ing thus a single row of arches. From about the beginning of the second quarter of the small intestine a second tier of arches, formed in a similar manner, is often noted, and below the middle of the jejunoileum more than two tiers of arches may be present, the complexity of the arches increasing, while the size of the vessels diminishes. From the convex border of the most distally placed arches there pass to the intestine straight branches, so-called **vasa recta**. Near the beginning of the jejunum these are numerous and large, and have a length of about 4 cm. and are quite regular. After the first third of the intestine is passed the vasa recta become smaller and shorter, and toward the lower end of the ileum they become short and irregular and are often less than 1 cm. in length (Dwight). The blood is returned by means of the superior mesenteric vein, which, with the splenic vein, forms the portal. The vascular arrangement in the intestinal wall is shown in fig. 941.

The **lymphatic** vessels form a continuous series, which is divided into two sets—viz., that of the mucous membrane and that of the muscular coat. The lymph-vessels of both sets form a copious plexus (fig. 941). The efferent lymphatic vessels form the so-called lacteals, which

FIG. 942.—MODEL SHOWING COURSE OF INTESTINE, MADE FROM SAME CADAVER FROM WHICH FIG. 943 WAS DRAWN. (Mall.)

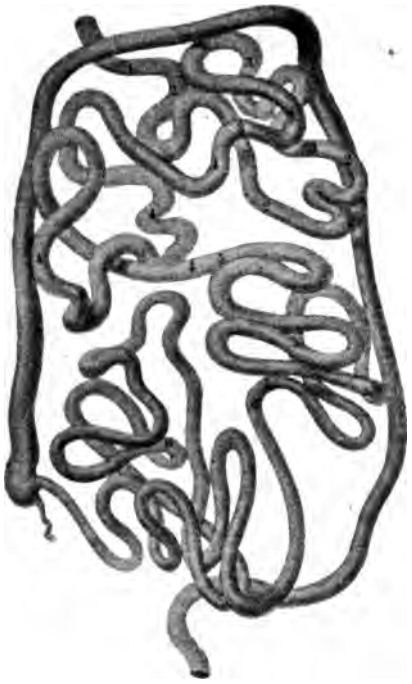

FIG. 943.—THE USUAL POSITION OF THE INTESTINE IN THE ABDOMINAL CAVITY. The numbers in the figure mark the parts which are homologous with the primary bends and groups of coils numbered from 1 to 6. (Mall.)

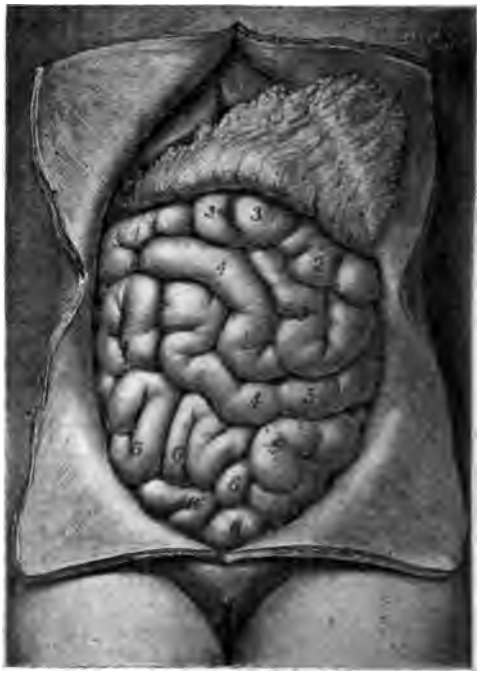


pass through the mesenteric lymph-nodes, finally reaching the cisterna (receptaculum) chyli.

The nerves.—The small intestine is supplied by means of the superior mesenteric plexus which is continuous with the lower part of the celiac (solar) plexus. The branches follow the blood-vessels, and finally form two plexuses: one (Auerbach's or myenteric) which lies between the muscular coats; and another (Meissner's) in the submucous coat. The nerve-fibers are chiefly from the sympathetic, partly from the vagus.

Development of the small intestine.—The early stages in the formation of the intestines have been described in Section I (p. 44), and also in connection with the *general morphogenesis* (p. 1173). Even in an embryo of 19 mm., while the intestine is still in the umbilical cœlom, Mall described six primary coils of the small intestine which could still be recognized after the return of the intestines to the general body cavity, and could usually be identified even in the adult (fig. 942). In the adult, as also through the various stages of development, loop 1 forms the duodenum. From the primary groups of coils marked 2 and 3 are developed the greater part of the jejunum, arranged in two distinct groups of loops, situated in the left hypochondriac region. The part of the intestine developed from group 4 of the primary coils passes across the umbilical region to the right upper part of the abdomen. That part developed from group 5 of the primary coils recrosses the median line to the left iliac fossa, while that part derived from group 6 of the primary coils is found in the false pelvis and the lower part of the abdominal cavity between the psoas muscles. They present what may be regarded as the normal arrangement of the small intestine, having been found 21 times in 41 cadavers examined. Variations from this arrangement occur; the great majority of such variations are, however, not of sufficient importance to require special mention.

According to Johnson (upon whose descriptions the following account is based), there is in embryos of 13 mm. to 23 mm. a formation of vacuoles in the duodenal epithelium, which leads to complete temporary occlusion of the lumen. A persistence of this condition may cause permanent atresia. In the epithelium of the small intestine numerous pockets or cysts occur, which usually disappear, but may persist and form permanent diverticula or accessory pancreas. The *villi* begin to appear at 19 mm., first in the mucosa of the upper portion of the intestine, as localized outgrowths which become arranged in longitudinal rows. The crypts of Lieberkuehn bud off from the epithelium at 55 mm., and from those in the duodenum, the duodenal (Brunner's) glands begin to bud off at 78 mm. The plicæ circulares begin to appear at the mid-region of the small intestine at 73 mm. The circular muscle-layer begins to appear at about 12 mm., the longitudinal at 75 mm.

Variations in the small intestine.—Although relatively fixed in position, the *duodenum* is quite variable in form. The C-shape previously described is the most common. When the pylorus and the duodenojejunal flexure are approximated, the form is nearly circular. When the two ends are more widely divergent, it approaches a U-form. Not infrequently, the inferior portion ascends abruptly from the inferior angle, giving a V-form. Finally, the terminal ascending portion may be very small or absent, in which case the duodenum approaches an L-form. Variations in the position of the various coils of the jejunum and ileum have already been discussed. The lymph-nodules, including Peyer's patches, like all lymphoid structures, are prominent during youth, but become atrophied in old age.

Meckel's diverticulum, which represents a derivation from the embryonic yolk-stalk and sac, is found in about 2 per cent. of all adults. It is a blind tube or diverticulum of variable size, usually approaching the intestine in width and averaging 5 cm. in length (ranging from 1 cm. to 13 cm.). Its attachment to the intestine varies from 15 cm. to 360 cm. (average 80 cm.) above the cecum. It is usually attached opposite the mesentery. It may end freely, but is occasionally adherent to adjacent intestinal coils or connected with the anterior abdominal wall by a cord or band-like process.

Other diverticula of variable size and number may occur, usually along the mesenteric border of the intestine. They may be either congenital (probably from the embryonic pockets previously mentioned) or acquired. They occur most frequently in the duodenum (found by Baldwin in 15 of 105 cases) where they are usually associated with the openings of the bile and pancreatic ducts.

Comparative.—The comparative anatomy of the small intestine will be discussed later together with that of the large intestine.

THE LARGE INTESTINE

The **large intestine** [intestinum crassum] is that part of the alimentary canal which extends between the ileum and the anus. It is divided into the following parts: Cecum, ascending, transverse, descending, and sigmoid colons, and rectum. It is so arranged as to surround the small intestine, making a circuit around the abdominal cavity from right to left (figs. 917, 948). The *cecum* lies in the right iliac fossa; thence the colon passes vertically upward on the right side (*ascending colon*) until the liver is reached. Here it forms a more or less rectangular bend (the right colic or hepatic flexure), and then passes transversely across the belly (*transverse colon*) below the stomach. It then reaches the spleen, where it makes a second sharp bend (the left colic or splenic flexure), and, passing vertically downward on the left side (*descending colon*), reaches the left iliac fossa. At this point it forms the loop of the sigmoid colon, and finally passes through the pelvis as the rectum (fig. 924).

Dimensions.—The large intestine is much larger in diameter than the small intestine, and is not so much convoluted. Excepting the dilated portion of the rectum, it is wider at the beginning than at the end. It varies in width at different parts from 3 to 8 cm. The length from the tip of the cecum to the point where the mesocolon ends is, in the male, about 140 cm., and in the female about 130 cm. The average total length, including the rectum, is about 150 cm. (5 ft.). The extremes found are 100 to 200 cm.

The large intestine, in all parts except the rectum, has a peculiar arrangement of its walls, which makes it in appearance very different from the small intestine. It is *sacculated*, and the sacculations [*haustra*] are produced by the gut having to adapt its length to three shorter muscular bands [*tæniæ coli*] which run the course of the intestine. These bands, which are about 12 mm. wide and 1 mm. thick, are really the longitudinal fibers of the muscular wall, which are chiefly collected along three lines (fig. 947).

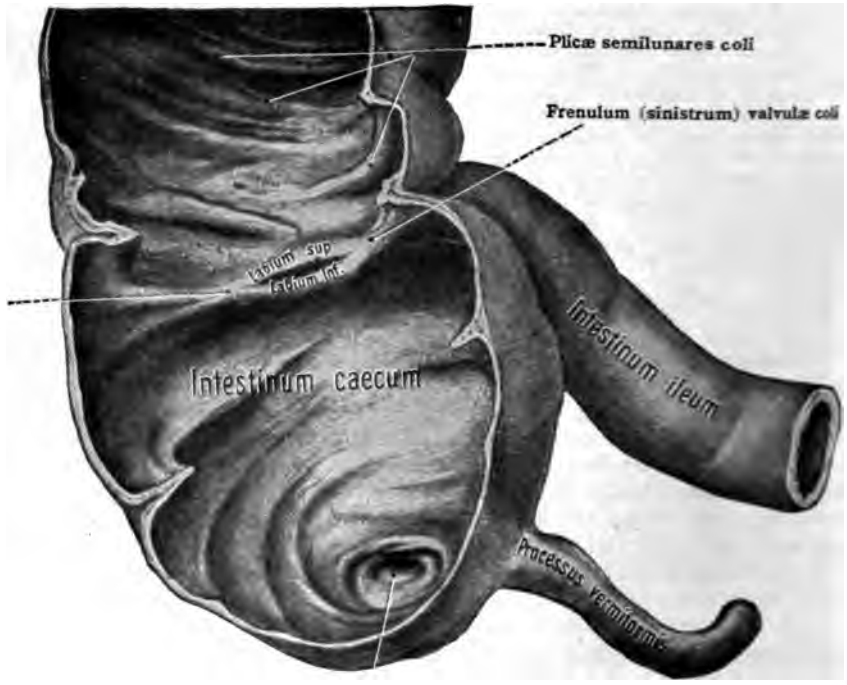
One band [*tænia mesocolica*], corresponding to the attachment of the mesocolon, is posterior on the transverse colon, and posteromedial on the ascending and descending colons. A second band [*tænia omentalis*] is anterosuperior on the transverse colon, elsewhere posterolateral. The third band [*tænia libera*] is free; it is inferior on the transverse colon, anterior elsewhere. All these bands start on the cecum at the vermiform process, and spread out to form a uniform layer on the rectum. Between the sacculations are *semilunar folds* [plicæ semilunares coli], which involve the entire thickness of the intestinal wall, forming crescentic ridges of the mucosa which project into the lumen (figs. 944, 947).

Along the free surface of the colon, especially near the teniæ, are numerous small appendages [*appendices epiploicæ*], which are pouches of peritoneum containing fat (fig. 294).

The cecum.—The cecum [intestinum cæcum] is a *cul-de-sac* forming the first part of the large intestine. It is defined as that part of the tube which is situated below the entrance of the ileum. Its breadth is about 7.5 cm., and its length about 6 cm. (fig. 944.) There is usually a more or less well marked constriction of the colon opposite the ileocecal orifice marking the boundary between cecum and colon. The cecum itself also sometimes presents a constriction dividing it into two sacculations.

It lies in the right iliac fossa, and is usually situated upon the iliopsoas muscle, and so placed that its apex or lowest point is just projecting beyond the medial border of that muscle (figs. 917, 924). It is usually entirely enveloped in peritoneum, and projects free in the peritoneal cavity, but is more or less adherent in

FIG. 944.—INTERIOR OF THE CECUM, ANTERIOR VIEW. (Rauber-Kopsch.)



Ostium et valvula processus vermiformis

about 10 per cent. of all cases. The apex of the cecum usually corresponds to a point a little to the medial side of the middle of the inguinal ligament. Less frequently the cecum will be found to be in relation with the iliacus muscle only; or the bulk of it will lie upon that muscle, while the apex rests upon the psoas. In some cases the cecum is entirely clear of both psoas and iliacus muscles, and hangs over the pelvic brim, or is lodged entirely within the pelvic cavity. Sometimes the cecum may pass even to the left of the median line of the body. This part of the intestine is also liable to marked variation in form.

The *variations* in the form of the cecum may be described under four types:

1. The fetal type is conical in shape, the appendix arising from the apex, and forming a continuation of the long axis of the colon. The three muscular bands which meet at the appendix are nearly at equal distances apart (fig. 945, A). When the cecum is empty and contracted it tends to approach this type.

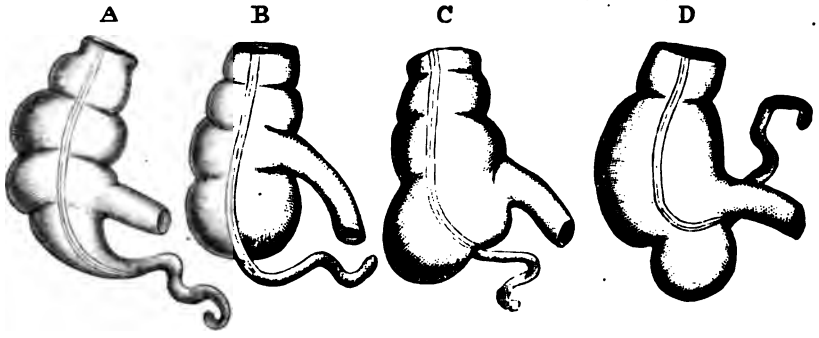
2. The second form is more quadrilateral in shape than the last; the three bands retain their relative positions; the appendix appears between two bulging sacculi, instead of at the summit of a cone (fig. 945, B).

3. In the third type, that part of the cecum lying to the right side of the anterior band grows out of proportion to that part to the left of the band. The anterior wall becomes more developed than the posterior, so that the apex is turned so much to the left and posteriorly

that it nearly meets the ileocecal junction. A false apex is formed by the highly developed part to the right of the anterior band. This is the usual cecum found (fig. 945, C).

4. In the fourth type, the development of the part to the right of the anterior band is excessive, while the segment to the left of the band has atrophied. In this form the anterior band runs to the inferior angle of junction of the ileum with the cecum. The root of the appendix is posterior to that angle. There is no trace of the original apex, and the appendix appears to spring almost from the ileocecal junction (fig. 945, D).

FIG. 945.—THE FOUR TYPES OF CECUM. (Treves.)



The ileocecal valve.—The ileocecal valve [valvula coli] is situated at the entrance of the ileum into the large intestine at the upper border of the cecum, on the posterior aspect and toward the medial side (fig. 944). The valve usually lies nearly opposite the middle of a line from the right anterior superior iliac spine to the umbilicus. The ileum passes from below upward and toward the right, and terminates obliquely. The valve is formed by two lip-like folds projecting into the large intestine, the upper [labium superius], and the lower [labium inferius]. They are not quite horizontal in direction (fig. 944). The opening between

FIG. 946.—RADIOGRAPH SHOWING CECUM AND UNUSUALLY LONG VERMIFORM PROCESS, EXTENDING INTO THE PELVIC CAVITY. (Dr. R. D. Carman, Mayo Clinic.)

them takes the form of a narrow transverse slit about 1.2 cm. in length. At the ends of the slit the valves unite and are prolonged at either end as a ridge [frenulum valvulæ coli] partially surrounding the intestine.

The efficiency of the valve in preventing the return of feces is due largely to its oblique position. (Symington.)

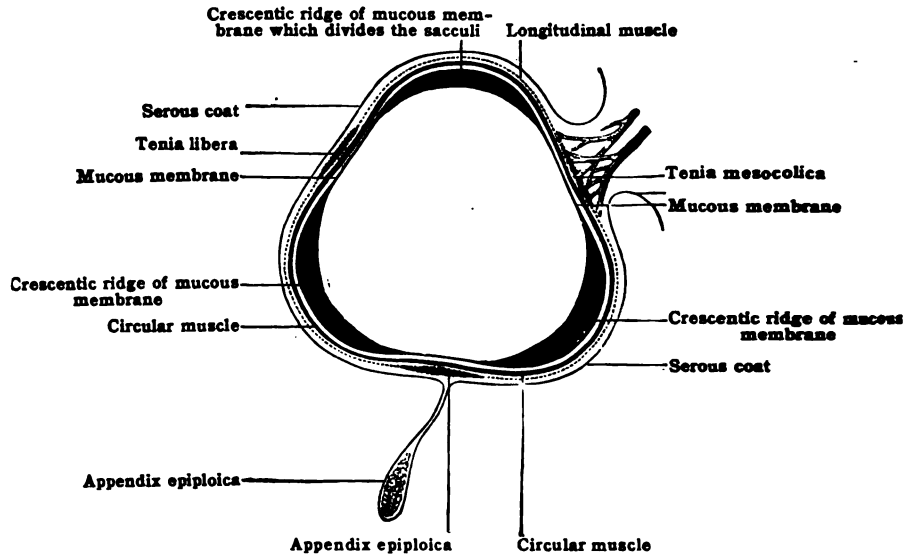
Villi cover that surface of the folds looking toward the ileum; the surface toward the large intestine is free from villi. In the formation of this valve the longitudinal muscular fibers pass across from the ileum to the large intestine without dipping down between the two layers of each fold. The circular muscular fibers, on the other hand, are contained between the mucous and submucous layers which form these folds.

Ileocecal fossæ.—About the cecum, and especially in the vicinity of the ileocecal junction, are certain fossæ collectively known as the ileocecal fossæ. Two only appear to be fairly constant, although a third is now and then present.

The first, the *superior ileocecal* or *ileocolic fossa*, is formed by the passage across the junction of the cecum and ileum of the anterior cecal artery, a branch of the ileocolic artery, which produces a fold of peritoneum [plica ileocolica] limiting a pouch. It is on the anterior aspect of the ileocolic junction, and the pouch opens downward (fig. 924). It is present in about one-third of all cases.

The second fossa is not quite so simple. If the cecum be turned upward so as to expose its posterior surface as it lies *in situ*, and if the appendix be drawn down so as to put its mesentery on the stretch, a peculiar fold will be found to join that mesentery. This fold arises from the border of the ileum opposite the insertion of its mesentery. It then passes over the ileocecal junction on its inferior aspect, is adherent to the cecum, and finally joins the surface of the mesentery of the appendix. This fold is peculiar in the absence of any visible vessels, and is often known as the 'bloodless fold of Treves.' Between it and the appendix there is an almost constant fossa, the *inferior ileocecal fossa*. It is usually large, admitting two fingers, and occurs in nearly 85 per cent. of all cases. It is bounded on one side by the small intestine, and on the other by the cecum. The appendix is occasionally found in the fossa.

FIG. 947.—CROSS-SECTION OF THE ASCENDING COLON. (Allen Thomson.)



The *subcecal* or *retrocolic* fossa is behind the cecum and is found in about 10 per cent. of all cases. It may extend for some distance behind the ascending colon. The appendix may be lodged in this fossa. *Paracecal* fossæ rarely occur, at the side of the cecum.

Variations.—In addition to variations already mentioned the cecum may vary in its general development. It is sometimes small and insignificant; in other cases it reaches a large size. It may be so rotated that the ileum passes behind the colon and opens on the right side. The posterior part has been seen much more developed than the anterior, so that the ileum has entered from the front, and the appendix has come off from the anterior wall. The cecum may remain undescended, and be found just under the liver or in the vicinity of the umbilicus. In case the rotation of the embryonic intestinal loop fails to occur (which rarely happens) the cecum may remain permanently upon the right side. If the normal process of adhesion fails to occur, the cecum and colon, along with the small intestine, may remain suspended from the middorsal line by the primitive *mesenterium commune*. Or any of the intermediate stages of partial adhesion may persist.

The vermiform process (appendix).—Attached to what was originally the apex of the cecum is a narrow, blind tube, the *vermiform process* [processus vermiformis] or *appendix*. It comes off at a variable distance (usually about 2.5 cm.) below the ileocecal valve on the posteromedial aspect of the cecum, though sometimes from the lower end of the cecum, or elsewhere. On the interior, at the point where it joins the cecum (fig. 944), there is a slight inconstant valve [valvula processus vermiformis]. The appendix joins the cecum at the point where the three teniæ meet, and the anterior tenia forms the best guide to this point. In the adult, the average length of the appendix is between 8 cm. and 10 cm., the extremes being 2 cm. to 25 cm. It is usually much twisted and coiled upon itself. Its direction is most frequently downward toward the pelvic cavity, or upward and medialward behind the ileum in the direction of the spleen. It occasionally turns lateralward, or more rarely upward behind the cecum.

The vermiform process does not have a true mesentery, but usually (in about 90 per cent. of cases) is provided with a falciform fold [mesenteriolum] or *meso-*

appendix of peritoneum, continuous with the left (lower) layer of the mesentery of the ileum (figs. 924, 1096).

In general outline this mesoappendix is triangular. In the adult it does not extend along the whole length of the tube. It is, in fact, too short for the appendix, and it is this that accounts for the twisted condition of this process. Along the free margin of the fold runs a branch of the ileocolic artery (fig. 1096).

The ascending colon.—The ascending colon [colon ascendens] (figs. 924, 933) extends in the right lumbar (lateral abdominal) region from the cecum to the inferior surface of the liver, lateral to the gall-bladder, forming there the right colic [flexura coli dextra] or hepatic flexure. Its average length is about 20 cm. (or somewhat less when measured *in situ*).

Peritoneal relations.—The ascending colon is covered by peritoneum in front and on the side (fig. 920), but in certain proportion of cases (26 per cent. according to Treves) this part of the large intestine is connected with the posterior wall of the abdomen by a mesocolon (usually very short) and is therefore surrounded by peritoneum. Connected with the ascending colon is sometimes found a fold of peritoneum, extending from the right side of the gut to the abdominal wall at a little above the level of the highest part of the iliac crest. It forms a shelf upon which rests the extreme right margin of the liver. It might be called the *sustentaculum hepatis*.

The ascending colon is in relation *behind* with the right kidney, and the iliacus and quadratus lumborum. *In front* are some of the coils of the ileum (fig. 917), separating it from the anterior abdominal wall.

The transverse colon.—The transverse colon [colon transversum], smaller in diameter than the ascending, extends from the lower surface of the liver to the spleen. Its average length is from 40 cm. to 50 cm. It describes an arch with its convexity forward and downward. It crosses through the umbilical region from the right hypochondrium to the left hypochondrium (figs. 917, 924, 933).

In the majority of cases the superficial part of the colic arch—as seen before the viscera are disturbed—is either in whole or in greater part above a straight line drawn transversely across the body between the highest points of the iliac crest. In about one-fourth of all cases it lies, in whole or in greater part, below this line.

Certain remarkable bends are sometimes formed by the transverse colon. The bending is always in the same direction, namely, downward, and is usually abrupt and angular. The apex of the V or U-shaped bend thus formed may reach the pubes. This bend appears to be due to various causes, including long-continued distention, congenital malformation, and movements of the stomach (to which it is attached by the gastrocolic ligament).

The transverse colon is in relation *above* with the liver and gall-bladder, the stomach, and at its left extremity with the spleen. The second portion of the duodenum passes *behind* it. *Below* are the coils of the small intestine. It is almost completely surrounded by peritoneum, being connected with the posterior abdominal wall (chiefly the anterior border of the pancreas) by the transverse mesocolon. This is usually lacking on the right of the midline, however, where the colon crosses the descending duodenum and the head of the pancreas (fig. 923).

The **descending colon** [colon descendens] is 25 cm. to 30 cm. in length (less when *in situ*) and extends from the spleen nearly to the pelvic brim (figs. 924, 1095). It is more movable than the ascending colon and is also narrower. At its beginning it is usually connected with the diaphragm, on a level with the tenth and eleventh ribs, by a fold of peritoneum, the *phrenocolic ligament* [lig. phrenicocolicum] (or *sustentaculum lienis*, from the fact that it supports the spleen). The bend between the transverse colon and descending colon is called the left colic or splenic flexure [flexura coli sinistra].

The descending colon is situated in the left hypochondriac, lumbar and iliac regions (fig. 924). Its relations to the peritoneum are the same as obtain with the ascending colon, that is, it is covered in front and on the sides. A mesocolon is met with oftener on this side than on the right, occurring in 36 per cent. of all cases (Treves) (see figs. 920, 923). It is found especially in the lower part of the descending colon, in the iliac fossa. This portion, extending from the iliac crest to the brim (superior aperture) of the pelvis, is sometimes described as a separate segment, the iliac colon (Jonnesco).

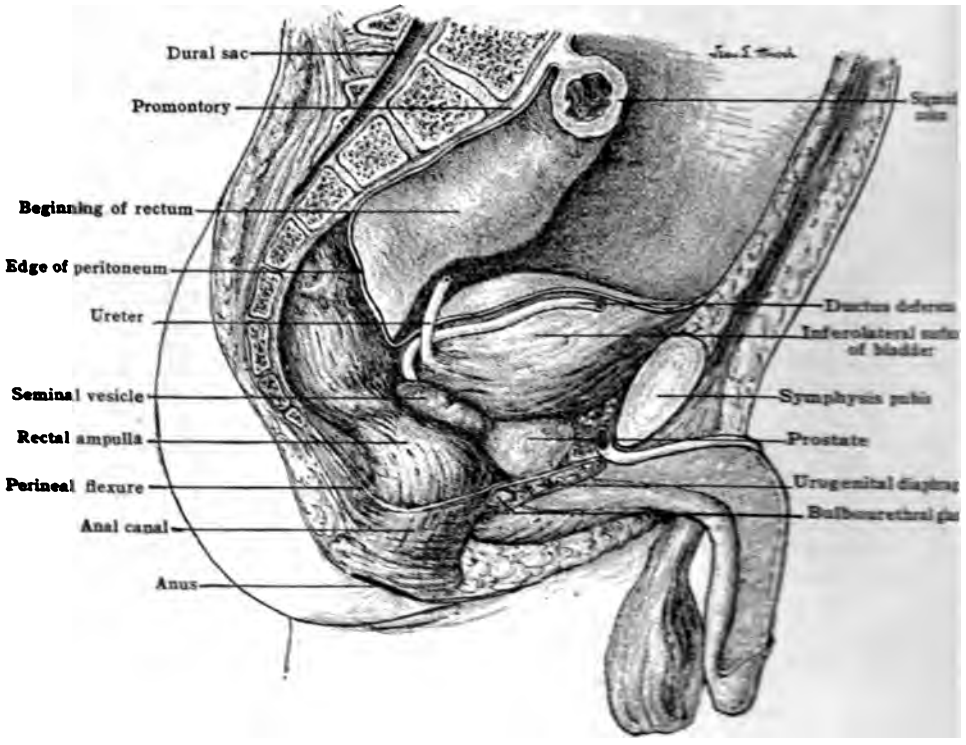
The descending colon is covered *anteriorly* by coils of small intestine; *posteriorly* it is in contact with the lower part of the left kidney, the quadratus lumborum, iliacus and psoas muscles. It terminates by crossing medialward over the psoas muscle and the external iliac vessels to join the sigmoid colon.

The **sigmoid colon** [colon sigmoideum] or pelvic colon, extends from the descending colon to the rectum (figs. 924, 948). It includes the parts formerly described as the 'sigmoid flexure' and the 'first portion' of the rectum. These together form a single loop which cannot conveniently be divided into parts.

Anteriorly is the bulb of the urethra and the posterior margin of the urogenital trigone in the male (fig. 950), while in the female it is separated from the vestibule and the lower part of the vagina by the 'perineal body' (fig. 951). *Posteriorly* it is connected with the tip of the coccyx by the anococcygeal body. *Laterally* it is in contact with the margins of the levatores ani, which act as an accessory sphincter, and help to support the ampulla recti.

The anus.—The anus is the aperture by which the intestine opens externally. During life it is contracted by the sphincters, so as to give the surrounding skin a wrinkled appearance. Around the lower part of the rectum and anus certain muscles that are connected with its proper function are situated. They are the internal sphincter, the levator ani, and the external sphincter. The levator ani and external sphincter will be found described in the section on MUSCULATURE. The *internal sphincter* is a thickening of the circular fibers of the rectum, situated around the second portion or anal canal. It forms a complete muscular ring 2 mm. to 3 mm. thick, and is composed of smooth muscle.

FIG. 950.—LATERAL VIEW OF THE MALE PELVIC VISCERA. (After His models.



Structure.—The rectum differs from the colon in having smoother walls and no appendices epiploicæ. At the upper end of the rectum, the tenia libera and tenia omentalis join to form a broad band which spreads out, covering the entire anterior aspect of the rectum. Similarly the tenia mesocolica spreads out upon the posterior aspect. Thus the rectum has a complete longitudinal muscle-layer, which, however, is thicker anteriorly and posteriorly than laterally. It sends a bundle of fibers to the coccyx, the rectococcygeus. Below, the longitudinal layer passes between the two sphincters and breaks up into numerous bundles which are interwoven with the external sphincter and levator ani, some of them terminating in the circumanal skin.

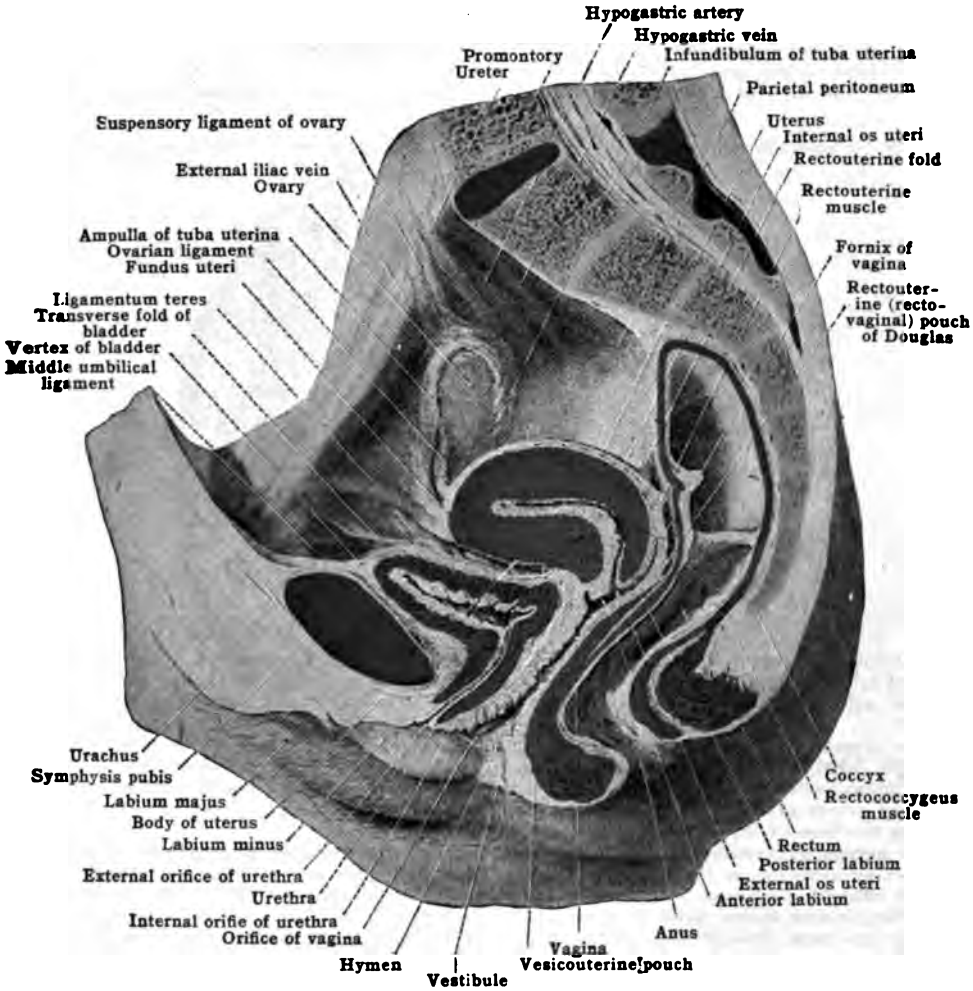
The rectal mucous membrane is thicker than that of the rest of the large intestine. [illegible] is chiefly longitudinal in direction, as seen in the lax state of the tube, which disappears when the rectum is distended. Its most characteristic feature are the permanent oblique **transverse folds**, some of which [illegible] (fig. 949), are formed by the mucous membrane and submucous tissue, which project into the lumen of the tube. One of these is on the right at the level of the reflection of the peritoneum from the rectum, and is [illegible] the right fold. That upon the right side is the largest [illegible] is sometimes called the [illegible]. It [illegible] is like the corresponding semilunar fold [illegible] wall.

[illegible] of the anal canal presents a series of vertical [illegible] rectal columns [illegible] of M[illegible] [illegible] [illegible] [

the small fossæ formed by them are known as the **rectal sinuses.** The area below the valves and extending to the anus is termed the *annulus hemorrhoidalis* (fig. 949). This is lined by a modified skin, while the area above the valves forms a transition to the typical mucosa of the rectum.

Minute structure of the large intestine.—In general, the large intestine has the four coats (fig. 952)—mucosa, submucosa, muscularis, and serosa—characteristic of the alimentary canal. The *mucosa* lacks the villi and plicæ circulares characteristic of the small intestine. It contains many solitary lymphatic nodules, but no Peyer's patches. It differs from the stomach in the absence of foveolæ, and in the presence of large numbers of mucous 'goblet cells' found both on the surface and along the numerous crypts of Lieberkuehn. The *submucosa* is much as in the small intestine. The *muscularis* has a continuous inner circular layer,

FIG. 951.—MIDSAGITTAL SECTION OF THE FEMALE PELVIS. (Spalteholz.)



the outer longitudinal fibers being chiefly gathered into the three bands, the teniæ coli, as above mentioned. The serosa is typical, excepting extraperitoneal areas where the epithelium is lacking. The appendices epiploicæ were also mentioned above. The cecum and colon present no special features worthy of mention, beyond the typical structure above outlined.

The *vermiform process* (appendix), however, differs in several important respects (fig. 953). The walls are relatively thick and the lumen small. The solitary lymph-nodules are closely packed or confluent (especially in young people). They occupy the greater part of the submucosa, and somewhat resemble the Peyer's patches of the ileum. They, like all the lymphoid structures in general, tend to become atrophied in old age. Fat cells are usually abundant in the submucosa. The *muscularis* presents an inner circular layer and also a thin but complete outer longitudinal layer. The serosa is typical. The lumen shows a progressive tendency to obliteration as age advances (Ribbert). This condition is never found in infancy but occurs usually (only partial) in over 25 per cent. of adults and in 50 per cent. of all cases over 50 years of age. It is, however, somewhat uncertain whether this represents a normal process. In obliteration, the glands and lymphoid nodules disappear, and the entire mucosa is transformed into an axial mass of fibrous connective tissue.

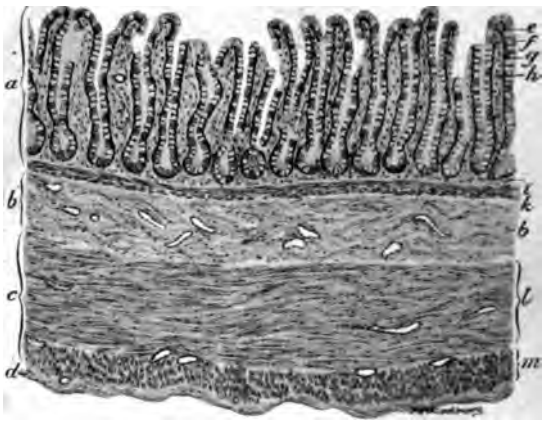
The *rectum* also presents several peculiarities of structure. Attention has already been called to the transverse folds (of Houston) and the rectal columns, sinuses and valves. Just above the valves, the mucosa is transitional, the epithelium being partly stratified, and the crypts of Lieberkuehn few and scattering. Below the valves, the annulus hemorrhoidalis is lined by a modified skin. Hairs and sebaceous and sweat-glands do not appear until just outside the anal orifice. The thickening of the circular muscle to form the internal sphincter, and the somewhat uniform disposition of the longitudinal muscle have already been mentioned as well as the absence of a serous coat in the lower portions.

Blood-vessels.—The large intestine is supplied with blood by the branches of the superior mesenteric and inferior mesenteric arteries, while it also receives a blood-supply from the internal iliac at the rectum. The vessels form a continuous series of arches from the cecum, where the vasa intestini tenuis anastomose with the ileocolic, the first branch of the superior mesenteric given to the large intestine.

The blood-supply of the rectum is from the inferior mesenteric by the superior hemorrhoidal, from the hypogastric (internal iliac) by the middle hemorrhoidal, and from the internal pudic by the inferior hemorrhoidal. The vessels at the lower end of the rectum assume a longitudinal direction, communicating freely near the anus, and less freely above.

The blood of the large intestine is returned into the portal vein by means of the superior mesenteric and inferior mesenteric veins. At the rectum a communication is set up between

FIG. 952.—CROSS-SECTION OF THE LARGE INTESTINE. *a*, Mucosa. *b*, Submucosa. *c*, Muscularis. *d*, Serosa. (Radasch.)



the systemic and portal system of veins, since some of the blood of that part of the intestine is returned into the hypogastric (internal iliac) veins. In the lower end of the rectum the veins, like the arteries, are arranged longitudinally. This arrangement is called the hemorrhoidal plexus.

The vermiform process (appendix) is supplied by a special branch of the ileocolic artery (figs. 523, 1096). This branch, the appendicular artery, crosses behind the terminal portion of the ileum (where pressure may obstruct the circulation) to enter the mesenteriolum. An accessory artery of small size also descends along the medial margin of the colon and cecum, entering the base of the appendix.

The **nerves** and **lymphatics** of the large intestine differ in no important particular from those of the small intestine, so far as their relations within the intestinal wall are concerned.

The efferent lymphatic vessels in general follow the blood-vessels and pass through corresponding lymph nodes in the various regions (see p. 769). Those of the cecum and vermiform process pass through the appendicular and ileocecal nodes; those of the colon through mesocolic and mesenteric nodes. Those of the descending and sigmoid colons connect with the inferior mesenteric and lumbar nodes. The superior zone of the rectum is drained by lymphatics passing to the anorectal and inferior mesenteric nodes; the middle zone (region of rectal columns) to nodes along the three hemorrhoidal arteries; the inferior zone (anal integument) chiefly to the superficial inguinal nodes.

Development of the large intestine. For the earlier stages, see Section I, p. 44, also *general morphogenesis*, p. 1173. The ascending and descending colons, the sigmoid mesocolon in part, and the rectum with corresponding portions of the mesorectum, become adherent to the posterior body wall during the fourth and fifth fetal months. At the same time, the posterior layer of the great omentum becomes fused with the upper (anterior) surface of the transverse mesocolon. The layer of retroperitoneal fascia corresponding to the obliterated mesocolon is shown in figs. 919, 920, 922, 1016. Variations in the process of fusion give rise to numerous peritoneal variations in the adult.

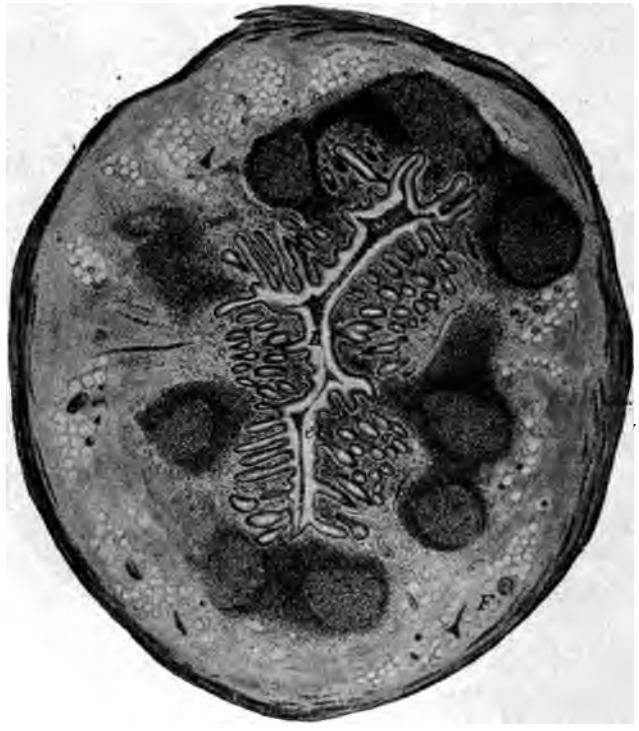
In fetuses of four to six months (length 100 mm. to 240 mm.) transitory villi appear in the mucosa throughout the large intestine, including the vermiform process. Their early obliteration is possibly due to distention of the gut by the meconium. The glands bud off like those of the small intestine. Lymphoid nodules are present abundantly in the vermiform process at birth (Johnson). The circular muscular-layer begins to appear in the lower part of the large intestine in embryos at 23 mm.; the teniæ at 75 to 99 mm. (F. T. Lewis.)

Development of the rectum and anus.—Earlier stages are described in Section I, p. 45. **Folds** of the mucosa representing the rectal columns, valves and sinuses appear in embryos **during** the the third month, and are well developed during the latter half of the fetal **period** (Johnson).

Variations.—The large intestine is exceedingly variable in its structure and relations, **especially** with reference to the peritoneum—so much so that it has been found more convenient **to** include a consideration of the variations along with the preceding description of the individual **parts**. The contents of feces (and gas) is as a rule relatively greatest in the cecum, decreasing **in** ascending and transverse colons. The descending colon is usually empty, or nearly so, the **sigmoid** colon and rectum somewhat variable. The rectal ampulla is usually more dilated in **women**.

Comparative.—The morphology of both small and large intestines will be briefly considered **here**. As previously mentioned, the primitive form of intestine is a comparatively straight **tube** extending from stomach to anus, and connected by a primitive mesentery to the mid-**dorsal** line of the body cavity. There is in many of the lower forms no clear division into small

FIG. 953.—TRANSVERSE SECTION OF THE HUMAN VERMIFORM PROCESS. (× 20.) (Stöhr and Lewis, from Sobotta.) Note absence of villi and abundance of lymph-nodules. *F*, Clusters of fat cells in submucosa. Only the inner part of the circular muscle is shown.



and large intestine, though the rectal region is usually more dilated, and opens into a cloaca. *Diverticula* often occur in the region between large and small intestine. In many fishes, numerous 'cæca' occur just below the pylorus, and in others an extensive *spiral valve* projects into the lumen of the intestine. The absorptive and digestive surface of the mucosa is further increased by the formation of various kinds of *folds*, and (beginning in amphibia) of *villi*. *Lymphoid tissue* is typically present in the mucosa, often localized in definite masses. Solitary nodules appear in amphibia, and Peyer's patches in birds. Tubular mucous glands occur in the lower forms, but Brunner's glands and crypts of Lieberkuehn apparently only in mammals. A *cecum* is usually present from the reptiles upward (double in birds), and often forms an important organ of digestion. The bile and pancreatic ducts open constantly a short distance below the pylorus. The small intestine is always longer than the large, but there is extreme variation in length among the various species. The four tunics—mucosa, submucosa, muscularis and serosa—are typical for vertebrates, the muscularis consisting of inner circular and outer longitudinal smooth muscle-fibers.

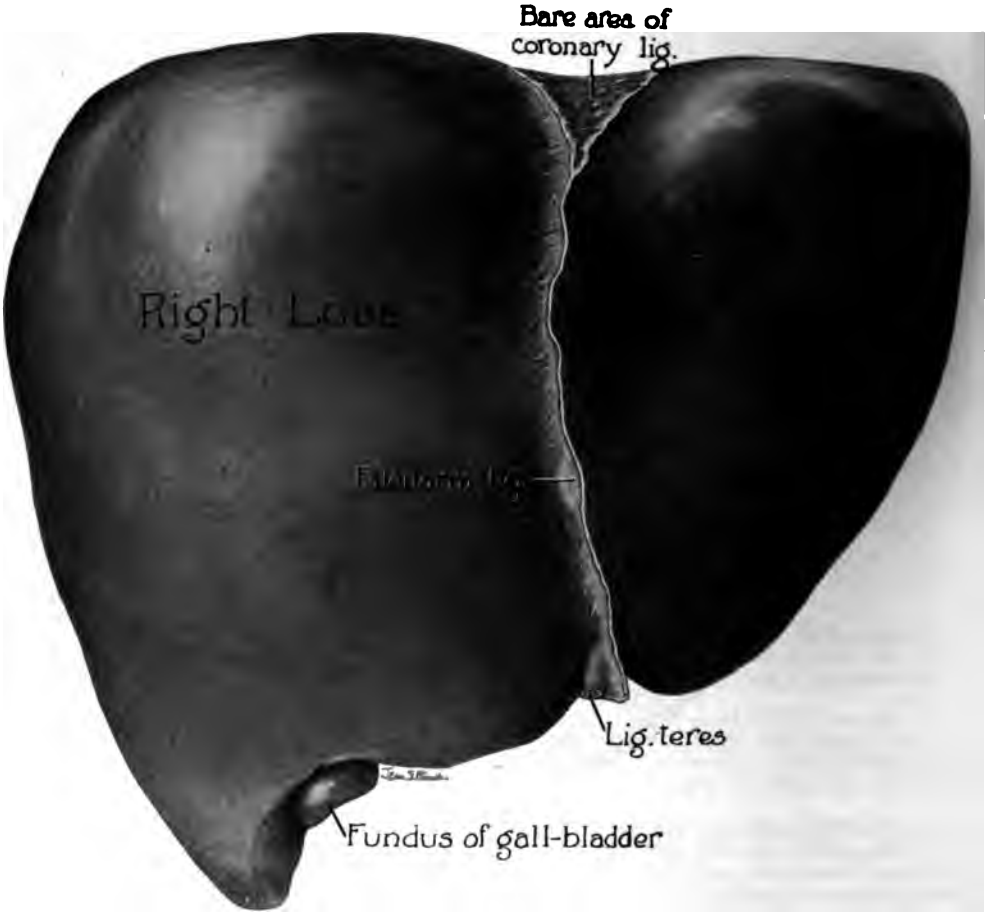
Among *mammals*, the divisions of the intestine correspond in general to those found in the human species, but there is exceedingly great variation in the relative development of the various parts. In general, the length, size and complexity of structure is relatively greatest in the *herbivora* (whose food is more difficult of digestion), least in the *carnivora*, and intermediate in the *omnivora*. Even in the same species, the structure of the intestine may be appreciably modified according to habitual diet. The large intestine varies, but is always shorter and wider than the small intestine. In mammals the rectum only is said to be homologous with the large intestine of lower vertebrates. The *cecum* is rarely absent and is enormously developed in herbivora. It often contains large amounts of lymphoid tissue, which, in pig and ox, forms a

so-called 'intestinal tonsil.' The *vermiform process* (found typically developed in man and higher anthropoids) apparently represents a retrogressive evolutionary change in the cecal apex, although this interpretation is denied by some (Berry), who interpret the appendix as a progressive, functional lymphoid organ.

THE LIVER

The **liver** [hepar] is the largest gland in the body. Its secretion, the bile [bilis; fel], is poured into the duodenum through the common bile-duct. In addition it has important functions as a 'ductless gland' in connection with the nitrogenous and carbohydrate metabolism. In form it is a variable somewhat irregular mass.

FIG. 954.—ANTERIOR VIEW OF THE LIVER.



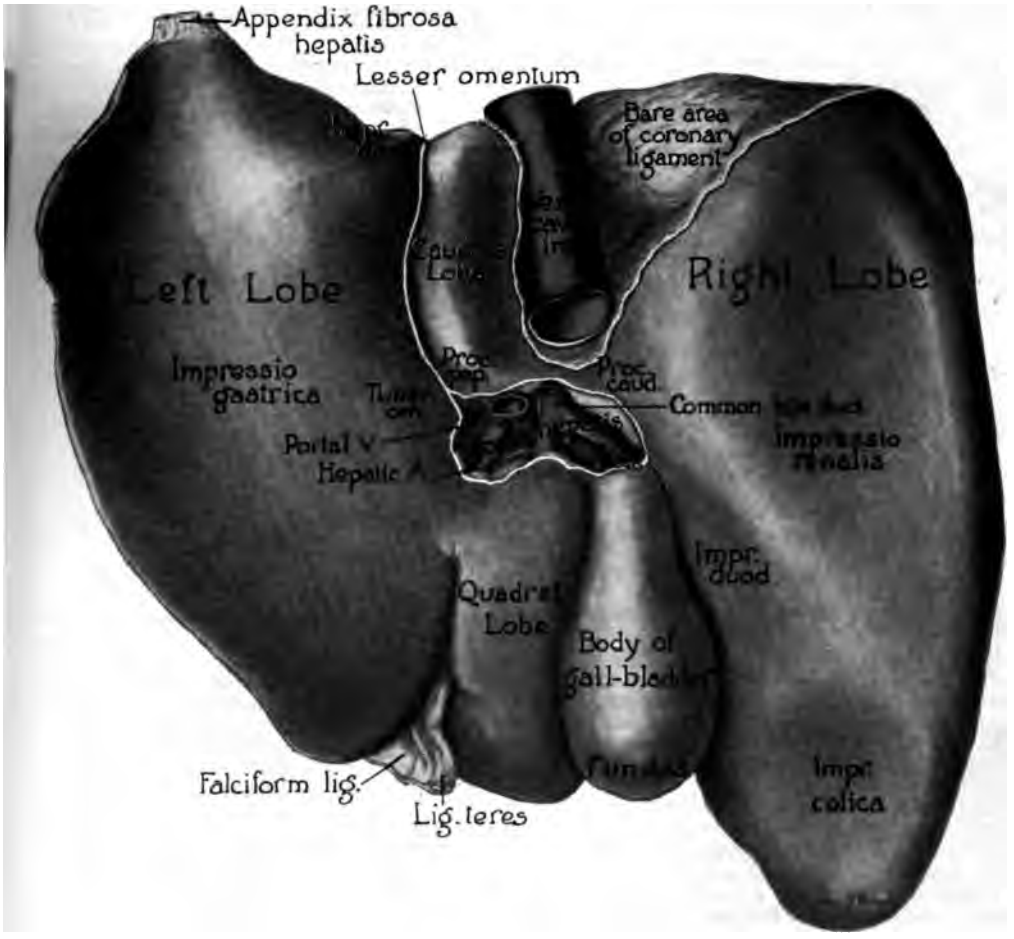
roughly comparable to a modified hemisphere occupying the upper right portion of the abdominal cavity (figs. 917, 1095). It presents a convex, rounded upper or *parietal* aspect, which is in contact with the diaphragm and adjacent body walls, and a lower, flattened *visceral* surface, in contact with the abdominal viscera. When viewed from the front, it is somewhat triangular in outline, occupying the right hypochondriac, the epigastric and (slightly) the left hypochondriac regions.

Physical characters.—In weight, the liver averages about 1500 gm. (3⅓ lbs.), but it is exceedingly variable, commonly ranging from 1000 gm. to 2000 gm. Its *relative* weight is also variable, averaging about 2.5 per cent. of the body in the adult male (somewhat higher in the female). Its *specific gravity* averages 1.056, so that the average weight of 1500 gm. would correspond to a *volume* of 1420 cc. Its *dimensions* are also quite variable. Its greatest *depth* (anteroposterior) averages about 15 cm., and its greatest *height* (vertical) is about the same. Its *width* (horizontal) is about 20 cm., while its greatest *length* (measured obliquely from side to side) averages about 25 cm. The color of the liver is a reddish-brown. It is firm in *consistency*, but friable, so that it is easily ruptured.

Surfaces and borders.—The most general division of the surface of the liver, as above stated, is into two—the parietal and the visceral. The parietal surface is again subdivided, usually into two surfaces—posterior and superior.

The **posterior surface** [facies posterior] is triangular (fig. 955). It is wide on the right, where the right lobe is in contact with the diaphragm (corresponding chiefly to the 'bare area' of the coronary ligament), and narrow on the left side, where the posterior margin of the left lobe is likewise attached to the diaphragm. Near the midline is the caudate (Spigelian) lobe, opposite the tenth and eleventh thoracic vertebral bodies, from which it is separated by the diaphragm (chiefly the right crus). On the right of the caudate lobe is the fossa lodging the vena cava

FIG. 955.—POSTERIOR VIEW (POSTERIOR AND INFERIOR SURFACES) OF THE LIVER.



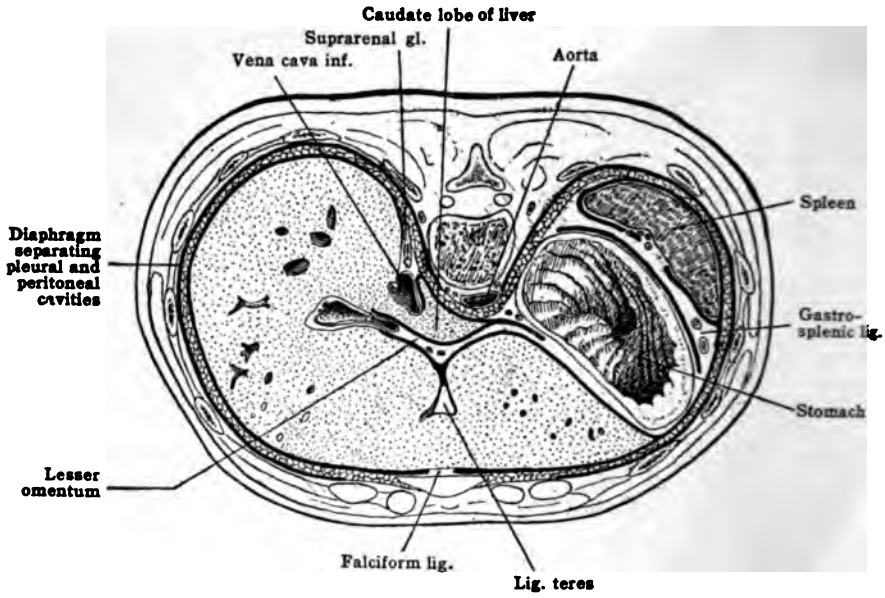
(sometimes bridged over), while to the left is the fissure of the ductus venosus, giving attachment to the upper portion of the lesser omentum (relations in cross-section shown in fig. 956).

The **superior surface** [facies superior] is in general convex and molded to the inferior surface of the diaphragm. It extends downward upon the anterior abdominal wall to a variable extent in the epigastric region, including the entire area of the liver visible from the front (fig. 954). It also presents a broad area extending downward on the right side. Symington accordingly distinguishes three surfaces corresponding to the superior surface above described, viz., right surface, anterior surface and superior surface. The superior surface is related above, through the diaphragm, with the base of the right lung, the pericardium and heart, and (on the extreme left) with the base of the left lung. Where it rests upon the liver, the heart forms a shallow fossa [impressio cardiaca].

The **inferior or visceral surface** [facies inferior] (fig. 955) faces downward and backward. It is irregularly concave, with impressions due to contact with the underlying viscera. It is divided into three lobes, right, left, and quadrate, whose relations will be described later.

Of the **borders,** the *anterior* [margo anterior] is the best marked. It forms the inferior boundary of the triangular anterior view of the liver (figs. 917, 954, 1095), and separates the superior (anterior) from the inferior surface. Slightly to the left of the midline, it usually presents a slight *umbilical notch* [incisura umbilicalis], where it is crossed by the falciform ligament. To the right of this there may also be a notch for the fundus of the gall-bladder (fig 954). The posterior surface is separated from the superior and inferior surfaces by ill-defined *posterosuperior* and *posteroinferior borders.*

FIG. 956.—CROSS-SECTION OF BODY AT LEVEL OF THE ELEVENTH THORACIC VERTEBRA (Poirier-Charpy.)



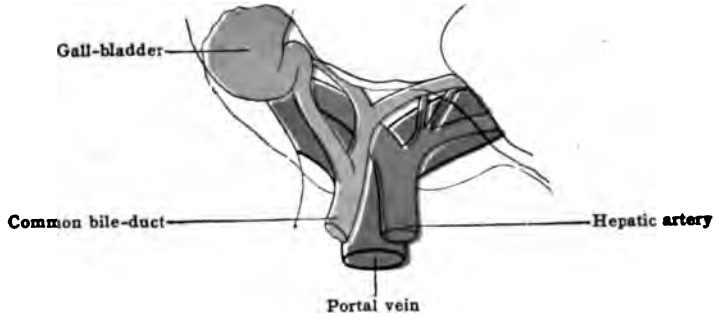
Surface-outline.—The average position of the liver may be outlined upon the anterior surface of the body as follows (fig. 1095): Locate one point on the right mammary (mid-Poupart) line opposite the fifth rib; a second point on the left mammary line about 2 cm. lower, in the fifth interspace; and a third point about 2 cm. below the costal arch (10th rib) on the right lateral wall. A line slightly concave upward, joining the first and second points, defines the uppermost aspect of the liver. A line, strongly convex laterally, joining the first and third points, defines the right side of the liver. Finally, a third line, joining the second and third points, corresponds to the anterior border and defines the lowermost portion of the liver. This line is subject to many individual variations. In general, it is usually slightly convex downward as it crosses the epigastric region. It usually presents a slight umbilical notch, as before mentioned, and frequently a notch for the fundus of the gall-bladder, which is placed near the right mammary (mid-Poupart) line. The lower and right portion of the anterior border of the liver runs somewhat parallel with the infracostal margin. In the upright position, and in livers larger than usual, it extends about 2 cm. below the hypochondrium into the right lateral abdominal (lumbar) region (fig. 1095). In the supine position however, the liver recedes about 2 cm. toward the head. The liver of course participates also in the respiratory movements of the diaphragm.

Lobes and fissures.—The superior surface is divided by the falciform ligament into two areas, corresponding to a larger right and a smaller left lobe (fig. 954). On the posterior and inferior surfaces of the liver (fig. 955), an **H-shaped arrangement** of fossæ and fissures completes the demarcation of lobes. The left upright of the H [fossa sagittalis sinistra] corresponds to the prolongation of the line of attachment of the falciform ligament. It is made up of the umbilical fissure [*fossa venæ umbilicalis*], containing the ligamentum teres, on the inferior surface; and of the *fossa ductus venosi*, containing the ligamentum venosum (obliterated ductus venosus) and the upper part of the lesser omentum, on the posterior surface of the liver. This left sagittal fossa separates the left lobe of the liver

the right lobe (in the wider sense of the term). The right lobe is further divided by the right upright and cross-bar of the H. The right upright [fossæ sagittales dextræ] is made up of the broad *fossa for the gall-bladder* [fossa vesicæ felleæ] on the inferior surface, and the broad *fossa venæ cavæ* on the posterior surface (fig. 955). These two fossæ are not continuous, but are separated by a narrow strip of liver, the caudate process of the caudate lobe. The cross-bar of the H is formed by the transverse or *portal fissure* [porta hepatis], which encloses the root structures of the liver, joining the right part of the lesser omentum (fig. 955). The area anterior to the cross-bar of the H corresponds to the quadrate lobe of the inferior surface; that posterior to the cross-bar to the caudate lobe of the posterior surface; while the remainder of the liver, to the right of the H, is the right lobe (in the narrower sense).

The right lobe [lobus hepatis dexter] makes up the greater part of the liver. Its relations on the superior and posterior surfaces have already been mentioned. On the inferior or visceral surface (fig. 955), there appears posteriorly a large concavity [impressio renalis] for the right kidney; medially a faint impression [impressio duodenalis] for the descending duodenum; and inferiorly a variable area [impressio colica] of contact with the right (hepatic) flexure of the colon. The caudate process joins the right with the caudate lobe.

FIG. 957.—RELATION OF STRUCTURES AT AND BELOW THE TRANSVERSE OR PORTAL FISSURE. ANTERIOR VIEW. (Thane.)



The left lobe [lobus hepatis sinister] lies to the left of the left sagittal fissure and the falciform ligament (fig. 955). It is flattened but variable in form and size, and makes only about one-fifth of the entire liver. In children and especially in early fetal life, it is relatively much larger. At the left extremity, there is usually found in the adult liver a variable fibrous band [appendix fibrosa hepatis] representing the atrophied remnant of the more extensive gland in earlier life. In this fibrous appendix (and in other parts of the liver) the bile-ducts of the atrophied liver substance persist as *vasa aberrantia hepatis*.

The left lobe is related *superiorly*, through the diaphragm, with the heart and the base of the left lung. *Inferiorly* (fig. 955) it presents a large concavity [impressio gastrica] which is in contact with the anterior surface of the stomach. Above and behind the gastric impression is the rounded *tuber omentale* which is placed above the lesser curvature of the stomach and related, through the lesser omentum, with a corresponding tuberosity on the pancreas. Above the gastric impression is a small inconspicuous groove [impressio œsophagea] for the abdominal part of the esophagus.

The **quadrate lobe** [lobus quadratus] lies, as before mentioned, on the inferior surface of the liver (fig. 955) in the anterior or inferior area of the H. It is in contact with the pylorus and the first part of the duodenum.

The **caudate** or **Spigelian lobe** [lobus caudatus; Spigeli] was described on the posterior surface of the liver (fig. 955). Inferiorly, the caudate lobe, behind the portal fissure, is divided by a notch into two processes. The left or *papillary process* [processus papillaris] is short and rounded, and lies opposite the tuber omentale. In the fetus it is relatively much larger and is in contact with the pancreas. The right or *caudate process* [processus caudatus] is of variable size, and joins the caudate with the right lobe of the liver. It is usually small and inconspicuous. In the fetus, however, it is relatively much larger, and extends downward to a variable extent behind the duodenum and head of the pancreas. In the adult, it forms the upper boundary of the epiploic foramen (of Winslow).

Peritoneal relations.—The liver in the adult is almost entirely surrounded by peritoneum. Although it develops together with the diaphragm in the common septum transversum (see p. 46 and fig. 963), the peritoneum soon extends in between liver and diaphragm, so that they remain in immediate contact only in the so-called 'bare area.' This is an irregular area on the posterior surface of the liver (chiefly on the right lobe), the margins of which correspond to the coronary ligament (figs. 923, 955). The posterior surface of the liver is therefore chiefly

retroperitoneal, excepting the caudate (Spigelian) lobe, which is in contact with the recessus superior of the bursa omentalis (fig. 923). The other surfaces of the liver are almost entirely covered with peritoneum, excepting the lines of attachment of the various peritoneal ligaments, and the fossa for the gall-bladder, which is usually directly in contact with the gall bladder with no intervening peritoneum.

Ligaments.—The liver is attached by five peritoneal ligaments—coronary, right and left triangular (lateral) and falciform ligaments and lesser omentum—and two accessory ligaments—teres and venosum.

The **coronary** ligament [lig. coronarium hepatis], as before mentioned, corresponds to the reflections of peritoneum from the liver to the diaphragm at the margins of the 'bare area' (figs. 923, 954, 955) on the posterior surface of the liver.

Within this uncovered area the hepatic veins join the inferior vena cava. The coronary ligament, though somewhat irregular and variable in form, is elongated laterally and roughly quadrangular. At the four angles, the peritoneal layers come together and are prolonged as four ligaments—right and left triangular (lateral) and falciform ligaments and lesser omentum. There is often also a special prolongation of the coronary ligament downward upon the right kidney, forming the *hepatorenal ligament* [lig. hepatorenale]. This lies to the right of the foramen epiploicum.

The **right triangular** (or lateral) ligament [lig. triangulare dextrum] is a short but variable prolongation of the coronary ligament to the right and downward (fig. 923). It connects the posterior surface of the right lobe of the liver with the corresponding portion of the diaphragm.

The **left triangular** (lateral) ligament [lig. triangulare sinistrum] is a longer, narrower prolongation of the coronary ligament to the left (fig. 923). It connects the posterior aspect of the left lobe of the liver with the corresponding portion of the diaphragm.

The **falciform** ligament [lig. falciforme hepatis] is a double layer of peritoneum representing (as before mentioned) the ventral portion of the primitive ventral mesogastrium (figs. 918, 923, 954).

Its upper end is continuous posteriorly with the coronary ligament. It passes forward and downward over the superior surface of the liver. From its line of attachment to the liver (between right and left lobes) it passes forward and slightly to the left to the attachment on the anterior body wall. This attachment extends downward slightly to the right of the midline to the umbilicus. The lower margin of the falciform ligament is free, and encloses the round ligament.

The **round ligament** [lig. teres hepatis] is a fibrous cord representing the obliterated fetal left umbilical vein. It extends upward from the umbilicus enclosed in the lower margin of the falciform ligament (figs. 954, 955).

At the anterior margin of the liver it passes backward on the inferior surface, enclosed in a slight peritoneal fold at the bottom of the fossa venæ umbilicalis (sometimes bridged over by liver tissue). It ends by joining the left branch of the portal vein.

The **ligamentum venosum** [lig. venosum; Arantii] similarly represents the obliterated fetal ductus venosus. It is a fibrous cord lying in the fossa ductus venosi, and extends from the left branch of the portal vein upward to the left hepatic vein near its opening into the vena cava. The ligamentum venosum lies within the hepatic attachment of the lesser omentum.

The **lesser omentum** [omentum minus] has already been discussed in connection with the peritoneum. It represents the dorsal part of the primitive ventral mesogastrium extending from the stomach to the liver. It includes two parts, as shown in fig. 924.

The upper and larger part forms the *gastrohepatic* ligament [lig. hepatogastricum], connecting the liver (fossa ductus venosi) with the lesser curvature of the stomach. The upper part of this ligament is somewhat thicker, the lower part thinner and more transparent. The relations of the lesser omentum in cross-section of the body are shown in fig. 921. The lower and right portion of the lesser omentum extends beyond the pylorus and connects the portal fissure with the duodenum, forming the *hepatoduodenal* ligament [lig. hepatoduodenale] (fig. 923). Its right free margin forms the anterior boundary of the epiploic foramen (of Winslow). Between its layers are located the root structures of the liver. A special prolongation of the hepatoduodenal ligament sometimes extends downward to the transverse colon, forming the *hepatocolic* ligament [lig. hepatocolicum].

Fixation of the liver. The liver is to a certain extent fixed in place by means of its various ligaments, and especially through the attachment of the hepatic veins to the inferior vena cava. On account of the close apposition of the liver to the diaphragm, the atmospheric pressure also helps in its support. Finally, the support of the liver, as well as of the abdominal viscera in general, is dependent to a considerable extent upon the tonic contraction of the abdominal muscles, which exerts a constant pressure upon the abdominal contents.

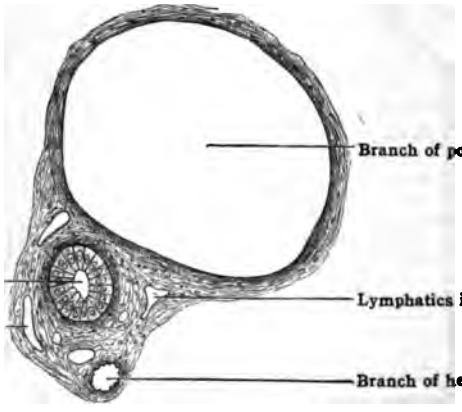
Blood-vessels.—The liver receives its *arterial* supply of blood from the hepatic artery, a branch of the celiac, which passes up between the two layers of the lesser omentum, and dividing into two branches, one for each lobe, enters the liver at the portal fissure. The right branch gives off a branch to the gall-bladder. The liver receives a much larger supply of blood from the *portal vein*, which conveys to the liver blood from the stomach, intestines, pancreas, and spleen. It enters the portal fissure, and there divides into two branches. Below this fissure the hepatic artery lies to the left, the bile-duct to the right, and the portal vein behind and between the two (fig. 957). These three structures ascend to the liver between the layers of the lesser omentum in front of the epiploic foramen. At the actual fissure the order of the three structures from before backward is—duct, artery, vein (fig. 955).

The *hepatic veins*, by which the blood of the liver passes into the inferior vena cava, open usually by two large and several small openings into that vessel on the posterior surface of the gland at the bottom of the fossa venæ cavæ.

Lymphatics.—The lymphatics are divided into a deep and a superficial set. The *deep set* runs with the branches of the portal vein, artery, and duct through the liver, leaving at the portal fissure, where they join the vessels of the superficial set. The efferent deep vessels after leaving the portal fissure pass down in the lesser omentum in front of the portal vein, through the chain of hepatic lymphatic nodes, and ultimately end in a group of nodes at the upper border of the neck of the pancreas, in which the pyloric lymphatics also terminate.

The *superficial set* begins in the subperitoneal tissue. Those of the *upper surface* consist: (1) Of vessels which pass up, principally, in the falciform ligament and right and left triangular ligaments, through the diaphragm, and so into the anterior mediastinal nodes, and finally into the right lymphatic duct. Some lymphatics of the right triangular ligament pass to the posterior mediastinal lymph-nodes and into the thoracic duct. (2) Of a set passing downward

FIG. 958.—SECTION OF A PORTAL CANAL. (Quain.)



over the anterior border of the liver to the hepatic nodes in the portal fissure, and over the posterior surface to reach the superior gastric and celiac nodes. On the lower surface, the lymphatics to the right of the gall-bladder enter the lumbar nodes. Those around the gall-bladder enter the hepatic nodes of the lesser omentum. Those to the left of the gall-bladder enter the superior gastric nodes.

Nerves.—The nerves of the liver are derived from the vagi (those from the left vagus entering from the stomach through the lesser omentum), and from the celiac plexus of the sympathetic (including right vagus branches) through a plexus accompanying the hepatic artery. The terminations, so far as known, are chiefly to the walls of the vessels and of the bile ducts.

Structure of the liver.—The liver is, for the greater part, covered by peritoneum, beneath which is found the fibroelastic layer known as Glisson's capsule. At the portal fissure, Glisson's capsule passes into the substance of the liver, accompanying the portal vessels, the branches of the hepatic artery, and the bile-ducts. The liver-substance is composed of vascular units measuring from 1 to 2 mm., and known as liver-lobules. These are in part (man) separated by a small amount of interlobular connective tissue, which is a continuation of Glisson's capsule. In this interlobular connective tissue are found the terminal branches of the portal vessels, the hepatic artery, and the bile-ducts (figs. 958, 959). The branches of the portal vessels which encircle the liver lobules are known as the interlobular veins. From these are given off hepatic capillaries, which anastomose freely, but have in general a direction toward the center of the lobule, and unite to form the central or intralobular veins, which in turn unite to form the sublobular veins, and these the hepatic veins. The intralobular branches of the hepatic arteries form capillaries which unite with the capillaries of the intralobular portal veins.

The liver is a modified compound tubular gland. The liver-cells are arranged in anastomosing cords and columns occupying the spaces formed by the hepatic capillaries. The bile-ducts have their origin in so-called bile-capillaries [ductus biliferi], situated in the columns of liver-cells; they anastomose freely and pass to the periphery of the lobules to form the primary divisions of the bile-ducts, and these unite to form the larger bile-ducts. The branches of the portal vessel are accompanied in their course through the liver by the branches of the hepatic artery and the bile-ducts, surrounded by extensions of Glisson's capsule forming the so-called

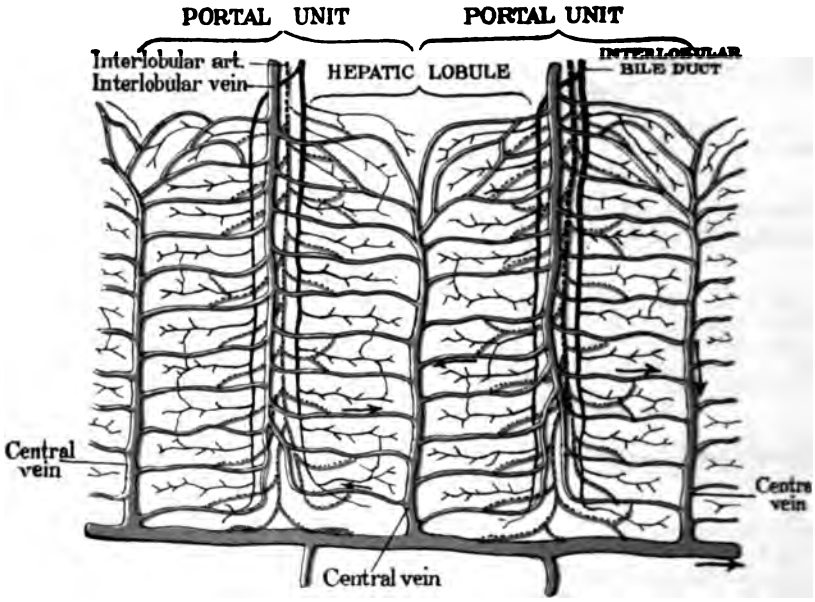
'portal canals' (fig. 958). The branches of the hepatic vein are solitary, their walls are and closely adherent to the liver substance, hence they remain wide open on sectioning liver.

While it is customary to describe thus the liver-lobules, it would be more logical to sider as the real lobules what Mall has described as the 'portal units.' Each portal unit inc the territory supplied by one interlobular branch of the portal vein, and drained by the acc panying bile-duct. The relations of the ordinary lobules and the portal units are evide fig. 959. The portal unit corresponds more nearly to the lobule of other glands, where duct is in the center of the lobule.

Bile-passages.—The bile-passages, which transmit the bile from the live the duodenum, include the gall-bladder, the cystic duct, the hepatic ducts, and common bile-duct.

The **gall-bladder** [vesica fellea], which retains the bile, is situated between right and quadrate lobes on the lower surface of the liver. It is pear-sha and (when full) is usually seen projecting beyond the anterior border of the l

FIG. 959.—DIAGRAM OF THE PORTAL UNIT AND VASCULAR RELATIONS OF THE HEPATIC LO (After Szymonowicz.)



(figs. 954, 955), coming in contact with the abdominal wall opposite the costal cartilage at the lateral margin of the right rectus muscle (fig. 109. extends back as far as the portal fissure.

It measures in length, from before backward, 7 to 10 cm. It is 2.5 to across at the widest part, and will hold about 35 cc. (1¼ oz.). The broad the sac is directed forward, downward, and to the right, and is called the The narrow end, or *neck* [collum vesicæ felleæ], which is curved first to the then to the left, lies within the lesser omentum at the portal fissure. The vening part is called the *body* [corpus vesicæ felleæ].

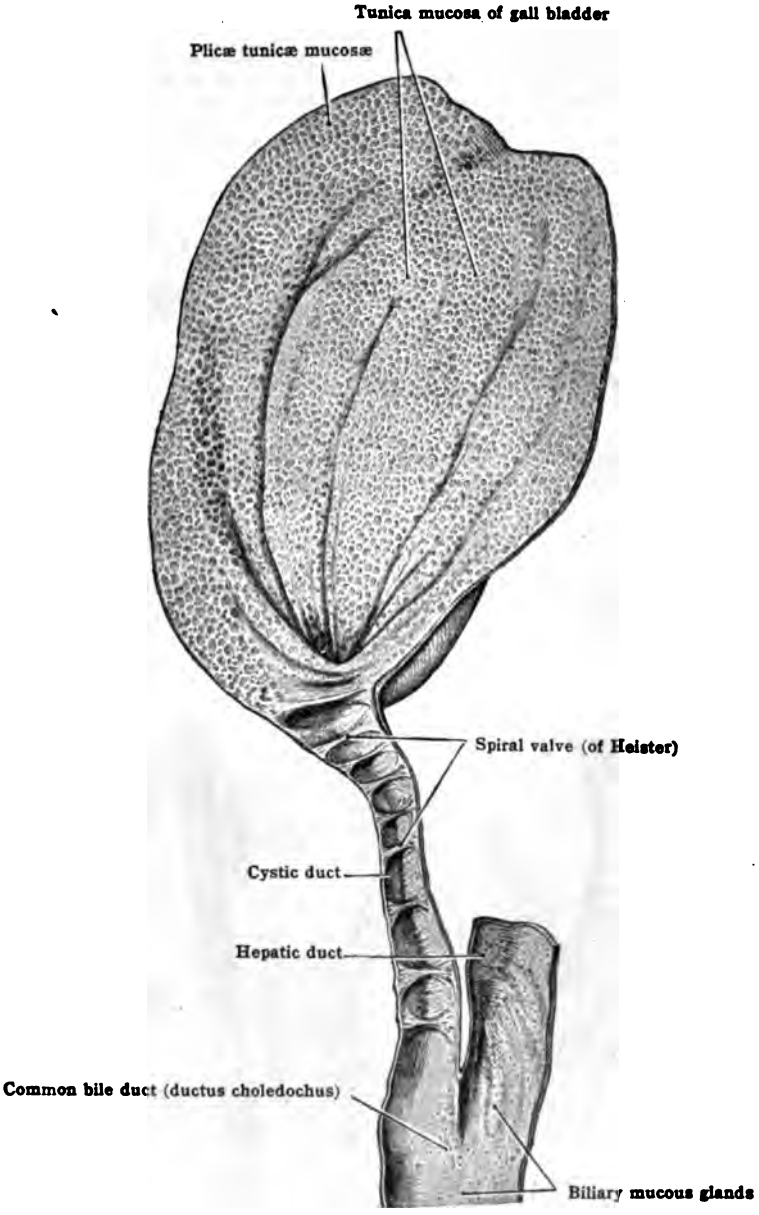
Its *upper surface* is in contact with the liver, lying in the fossa of the gall-bladde attached to the liver by fibrous connective tissue. The lower surface is covered by peri which passes over its sides and inferior surface, though occasionally it entirely surrounds bladder, forming a sort of mesentery attaching to the liver. The *lower surface* comes i tact with the first part of the duodenum and the transverse colon, and occasionally pyloric end of the stomach or small intestine, which *post mortem* are often found stai bile.

The neck of the gall-bladder opens into the *cystic duct* [ductus cy This is a tube about 3.5 cm. long and 3 mm. wide, which unites with the duct to form the ductus choledochus; it is directed backward and to th it runs in the lesser omentum, the common hepatic artery being to the l the right branch of the artery and portal vein behind (fig. 955). It jo

epatic duct at an acute angle, and is kept patent by a spiral valve [valvula piralis; Heisteri], formed by its mucous coat (fig. 960).

The *hepatic duct* [ductus hepaticus] begins with a branch from each lobe, right and left (that from the left receiving also the ducts from the caudate lobe), in the portal fissure, and is directed downward and to the right within the portal fissure and the lesser omentum (hepatoduodenal ligament), the right branch of

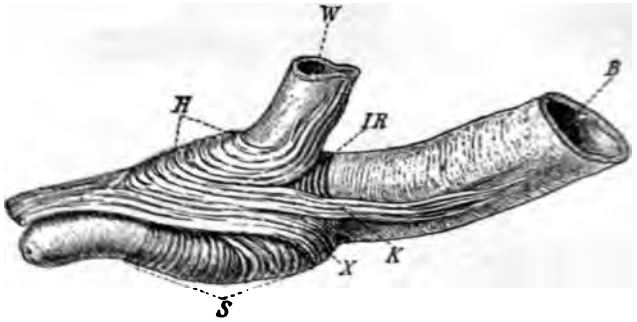
FIG. 960.—INTERIOR OF THE GALL-BLADDER AND DUCTS. (From Toldt's Atlas.)



the hepatic artery being behind and the left branch to the left. It is from 3 to 5 cm. long; its diameter is about 4 mm. Uniting with the cystic duct, it forms the *common bile-duct* [ductus choledochus].

The **ductus choledochus** or **common bile-duct** is about 7.5 cm. in length and 6 mm. in width. It passes down between the layers of the lesser omentum, in front of the portal vein, and to the right of the hepatic artery (fig. 957); it then passes behind the first part of the duodenum, then between the second part and the head of the pancreas, being almost completely embedded in the substance of

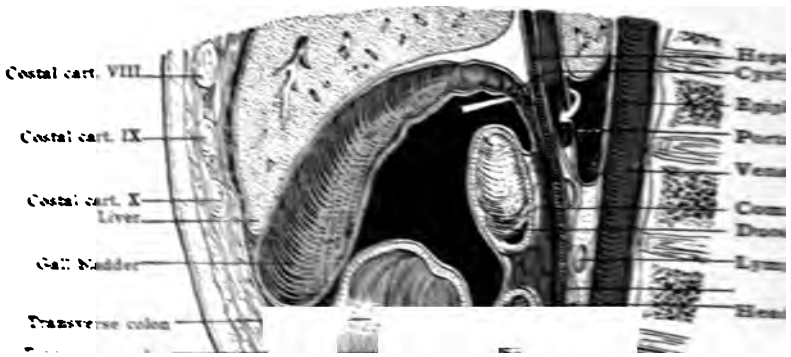
CULATURE. *B*, Common bile-duct. *W*, Pancreatic duct (of Wirsung). *S*, fibers of bile-duct. *H*, Fibers of pancreatic duct. (Hendrickson.)



In its oblique course through the duodenal wall, the common bile-duct is the pancreatic duct, the two together usually causing the plica longitudinalis du muscle fibers join with bundles of longitudinal fibers at the lower part of the sphincter around each (fig. 961). Contraction of the sphincter probably closes common bile-duct, so that except during digestion the bile is backed up into

Structure of the gall-bladder.—The wall of the gall-bladder is made up mucosa, fibromuscular and serosa.

FIG. 962. RELATIONS OF GALL-BLADDER AND BILE-DUCTS IN SAGITTAL SEC grammatic. After Testut and Jacob.)



he *serosa*, formed by the peritoneum, is found only on the sides and lower surface. *ducts* consist of a fibromuscular and a mucous layer. In the fibromuscular layer are muscle-cells which are chiefly circular, together with white fibrous tissue and elastic The lining mucosa has many mucous glands. In the cystic duct the mucous membrane into folds, which are crescentic in form, and directed so obliquely as to seem to surround en of the tube in a spiral manner.

development of the liver.—For the earlier stages, see Section I, p. 46. The definite lobules are not differentiated until after birth. The process of the development of the is very complicated, the vascular arrangement being shifted repeatedly (Mall).

embryonic liver rapidly enlarges, filling the upper portion of the abdominal cavity, and ıg along its ventral wall to the region of the umbilicus. During the enlargement it 's the transverse septum (fig. 963), and there are developed grooves which result in an g of the peritoneum covering the transverse septum, and which in part separate the ing liver from that part of the septum destined to form the diaphragm, and also from the abdominal wall. These grooves appear at the sides and also ventral to the liver, but do pletely separate the liver from the diaphragm, nor do they meet in the median line. A of the liver, therefore, remains uncovered by peritoneum, and remains attached to the gm by the 'bare area' of the liver. Around this area the peritoneum of the liver is

3.—DIAGRAM: (A) A SAGITTAL SECTION OF AN EMBRYO SHOWING THE LIVER ENCLOSED THIN THE SEPTUM TRANSVERSUM; (B) A FRONTAL SECTION OF THE SAME; (C) FRONTAL TION OF A LATER STAGE WHEN THE LIVER HAS SEPARATED FROM THE DIAPHRAGM.

l on to the diaphragm, forming the coronary ligament, with right and left extensions, ed as the right and left triangular ligaments. Where the grooves fail to meet in the midline, there persists a fold of peritoneum, the falciform ligament, which represents the portion of the primitive ventral mesentery and attaches the liver to the ventral abdom- l. The dorsal portion of the ventral mesentery (mesogastrium) persists between the l stomach to form the lesser omentum. The developing liver early comes into intimate with the omphalomesenteric vitelline veins, and later the umbilical veins. The develop- history of these veins and their relation to the developing liver is discussed elsewhere 33). After birth the left umbilical vein forms the hepatic ligamentum teres, situated ee edge of the falciform ligament. The ductus venosus likewise atrophies to form the tum venosum. For the growth of the liver and gall-bladder, see p. 46.

ıtions of the liver and bile-passages.—Many variations of the liver have already ntioned. In *size*, both relative and absolute, it is subject to marked individual varia- well as according to age and sex (previously described). In *form*, the liver is also quite . There are two extreme types: (1) in which the liver is very wide, extending far over left hypochondrium, but relatively flattened from above downward; and (2) in which it but slightly to the left, being somewhat flattened from side to side, and elongated y. This type may occur as a result of tight lacing, in which the liver is frequently d. The part projecting below the right costal margin may form the so-called '*Riedel's* ll intermediate forms between these two types occur. Its *position and relations* will y necessarily according to differences in size and shape. For example, in the wide type in enlarged livers, the left lobe may extend over upon the spleen, a relation which is ; during prenatal life.

e may be *supernumerary fissures*, dividing the liver into additional lobes, as many as ıg been described in an extreme case (Moser). These extra fissures often correspond es which are normal in other mammals. There may also be *accessory lobes*, usually nd connected with the main gland by stalks. Any one of the normal lobes may be *l* or absent. There may also be *abnormal grooves* on the parietal surface of the liver. , there are two varieties: (1) *costal* grooves, due to impressions of the overlying ribs al cartilages; and (2) *diaphragmatic* grooves, due to wrinkles in the diaphragm. These most frequently occur in females, as a result of tight lacing. The *appendix fibrosa* ıdy been mentioned. There are numerous variations in the *vascular* arrangements, as n the *peritoneal* relations (particularly in connection with the coronary ligament).

acter becomes masked, however (in amniota, and especially in mammals), by
anastomosis between the tubules, forming what is called a 'solid' gland. The
the portal venous system are constant. The liver frequently stores large quantiti

In *size*, the liver is variable, but is usually relatively larger in anamniota. Amo
there is great variation according to diet, the liver being relatively larger in carni
in herbivora, and intermediate in omnivora (including man). It is also relatively l
animals (including young and fetal stages), probably on account of their more int
lism. There are typically two lobes, right and left, in the vertebrate liver. T
quently subdivided, however, especially in mammals, which often present numer

The **gall-bladder** is typically present, as in man, but varies in form, size and
may be completely buried in the liver. In some species it is absent, in which cas
ducts open directly into the duodenum by one or more apertures. The hepat
ducts typically unite to form a common bile-duct, as in man, but there are numero
in the detailed arrangement of the ducts.

THE PANCREAS

The **pancreas** (figs. 935, 936, 964, 965, 966) is an elongated glan
transversely across the posterior abdominal wall behind the stomac
duodenum to the spleen. Through the pancreatic ducts, opening i
scending duodenum, flows its secretion [succus pancreaticus].

The pancreas is grayish-pink in color. Its average length (*in situ*) i
15 cm.; average weight about 80 gm. (extremes 60 gm. to 100 gm.
Its specific gravity, 1.047, is about the same as that of the salivary gla

In *position*, the pancreas lies in the epigastric and left hypochondri
In *form* it somewhat resembles a pistol, with the handle placed to th
the barrel to the left. The pancreas is accordingly divided into a
within the duodenal loop; a *body*, extending to the left; and a *tail*,
extremity.

The **head** [caput pancreatis] is a discoidal mass somewhat elongated
and flattened dorsoventrally. It forms the enlarged right extremity
creas and lies within the concavity of the duodenum (figs. 935, 936,
relations are as follows: Its *posterior* surface is placed opposite the s
third lumbar vertebra, and is in contact with the aorta, the vena cava
veins and right renal artery. The common bile-duct is also partly
in this surface. Its *anterior* surface is crossed by the transverse co
which is the pyloric extremity of the stomach, and below which a
small intestine. Upon this surface are also the pancreaticoduoden
part) the superior mesenteric vessels.

The junction of the upper and left aspect of the head with the body of the pancreas is called the *neck*. This is a somewhat constricted portion grooved *posteriorly* by the superior mesenteric vessels, the vein here joining with the splenic to form the portal vein (fig. 936). *Anterior* to the neck is the pyloric portion of the stomach. The upper portion of the neck (together with a variable area on the left end of the body) projects above the lesser curvature of the stomach. This projection [*tuber omentale*] is related, through the lesser omentum, with a similar tuberosity on the left lobe of the liver. The anterior aspect of the neck is covered with peritoneum of the bursa omentalis (lesser sac), and is continuous with the anterior surface of the body of the pancreas (fig. 935).

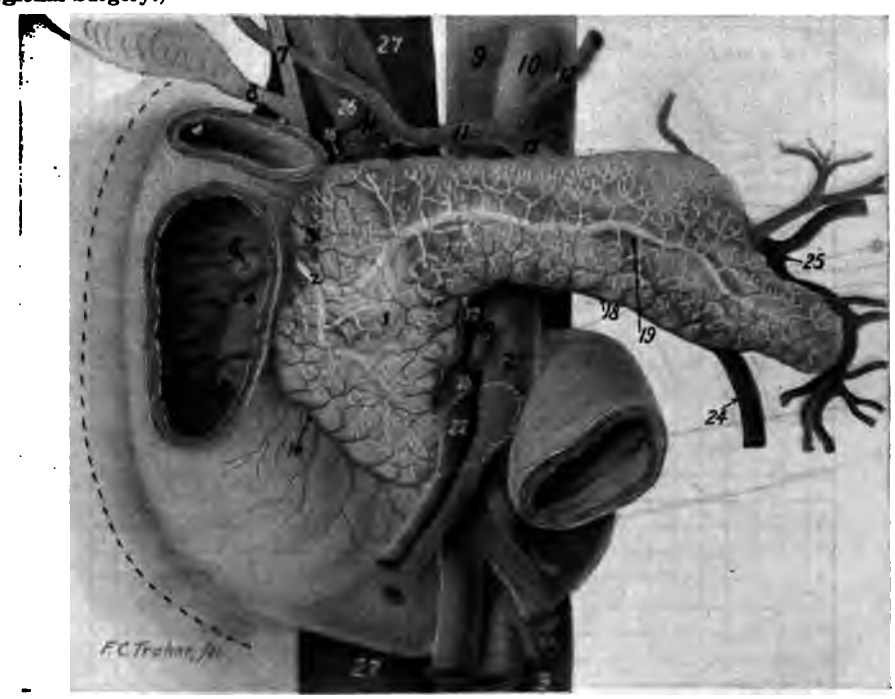
Black dotted line indicates site for mobilizing duodenum. White dotted line including 22 represents position of uncinate process running behind mesenteric vessels. (Coffey; in Binnie's Regional Surgery.)



The **body** [corpus pancreatis] is the triangularly prismatic portion of the pancreas extending from the neck on the right to the tail on the left. Its *direction* is transversely to the left and (usually) somewhat upward. It is therefore usually placed at a somewhat higher level than the head, opposite the first lumbar vertebra. It presents three surfaces—anterior, posterior, and inferior—and three borders—superior, anterior, and posterior.

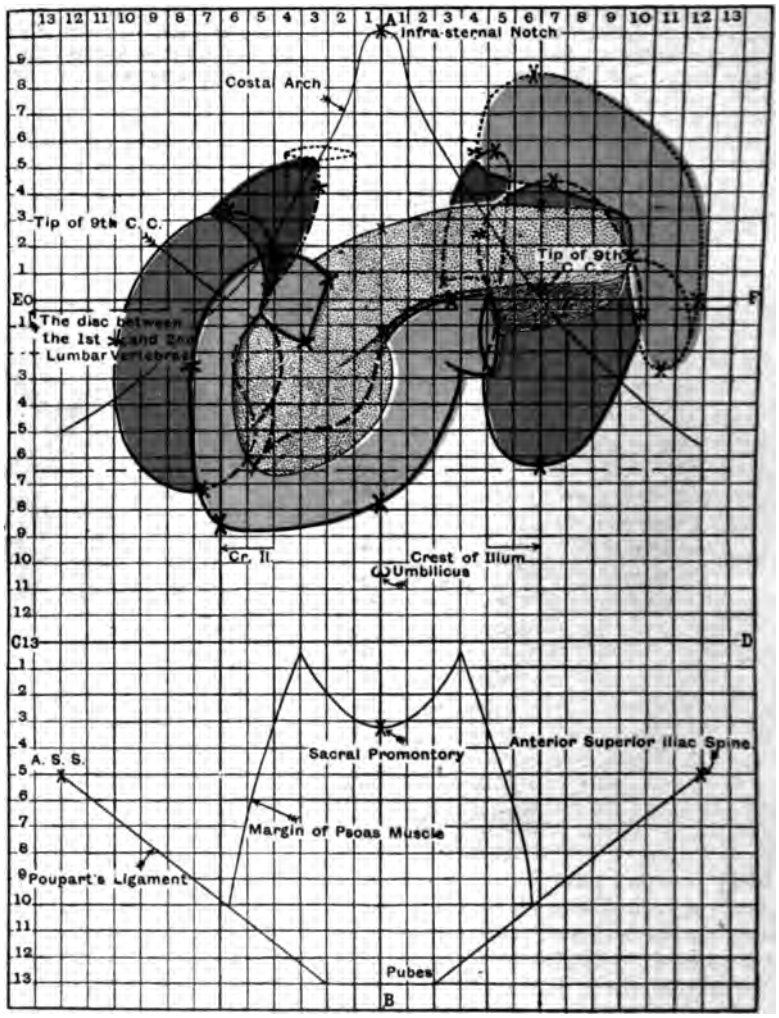
Of the **surfaces,** the **anterior** [facies anterior] faces forward and somewhat upward. It is covered with the peritoneum of the posterior wall of the bursa omentalis (lesser sac), and forms a slightly concave area which is in contact with the posterior surface of the stomach (figs. 636, 922, 924, 933). The **posterior** surface [f. posterior] of the body of the pancreas is flattened and retroperitoneal. From right to left it crosses the anterior aspect of aorta, left suprarenal body and left kidney. The splenic vessels also run along the posterior surface, the artery, which is above, corresponding more nearly with the superior border. The **inferior** surface [f. inferior] is usually the narrowest of the three. It is covered by peritoneum (continuous with the lower layer of the transverse mesocolon) and is in

contact with the duodenojejunal flexure medially and with coils of jejunu laterally.

Of the **borders,** the **superior** [margo superior] is related with the splenic arte along its whole length from its origin in the celiac, and the **posterior** [mar posterior] separates posterior and inferior surfaces. The **anterior** border [mar anterior] is sharp and prominent. It gives attachment to the transverse me colon (fig. 636), whose upper layer (belonging to the lesser sac) is continuous wi that on the anterior surface of the pancreas, and whose lower layer (belonging the greater sac) is continuous with that on the inferior surface.

The **tail** of the pancreas [cauda pancreatis] is at the left extremity of the bod It is variable in form, but usually somewhat blunted and upturned. It is almo

FIG. 965.—OUTLINE SHOWING THE AVERAGE POSITION OF THE DEEPER ABDOMINAL VISCE IN 40 BODIES, ON A CENTIMETER SCALE (reduced to 0.36 natural size). *AB*, anterior midli *EF*, 'midepigastric' line. (Addison.)



invariably in contact *laterally* with the medial aspect of the spleen, and *inferiorl* with the splenic flexure of the colon. The splenic vessels often cross from abov in front of the tail of the pancreas on their way to join the spleen.

Ducts.—The pancreas has usually two ducts, the main pancreatic duct and th accessory duct. The *main pancreatic* or *duct of Wirsung* [ductus pancreaticus Wirsungi] begins in the tail of the pancreas, and extends to the right within th body of the pancreas, about midway between upper and posterior borders, bu nearer the posterior surface (fig. 964). It runs a slightly sinuous course receivin branches all along, which enter nearly at right angles. It is largest in the hea of the pancreas (diameter about 3 mm.) where it turns obliquely downward.

As the pancreatic duct approaches the duodenum, it is joined by the common bile-duct, the two running side by side. They pass obliquely through the wall of the duodenum for a distance of about 15 mm. (usually causing a fold of the mucosa, the plica longitudinalis duodeni). They terminate finally, usually by a common aperture, but sometimes separately, on the duodenal *papilla major*, as described in connection with the interior of the duodenum. The common aperture is somewhat narrow, but just preceding this the duct is frequently dilated, forming what is called the *ampulla of Vater*.

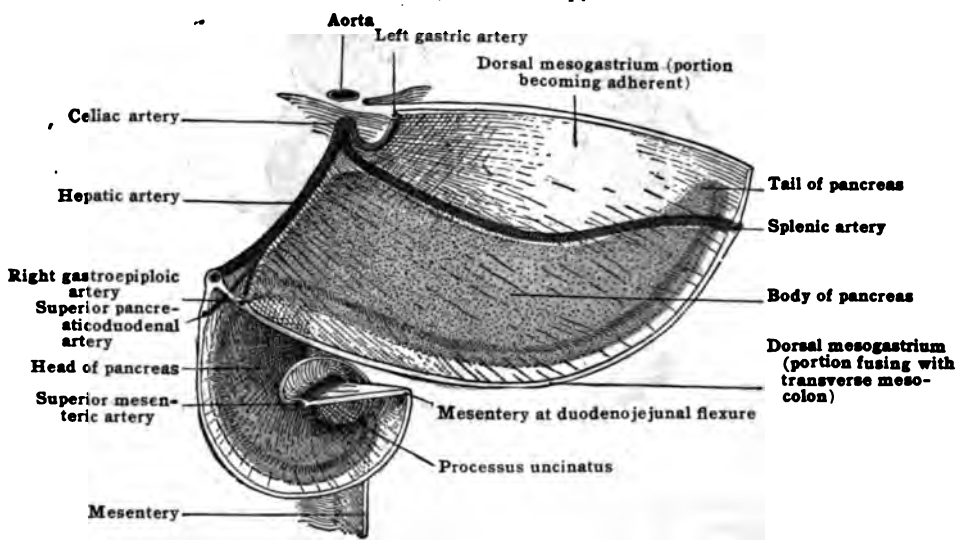
The *accessory pancreatic duct* (duct of Santorini) is usually present (fig. 964), but variable. This duct is small, and lies within the head of the pancreas.

At its left end, it usually joins the main duct in the neck of the pancreas. From here it extends nearly horizontal across to the upper part of the descending duodenum and, piercing its wall, usually ends upon the small *papilla minor*, about 2 cm. above and slightly ventral to the papilla major. The relations of the ducts are explained by its development.

Blood-vessels.—The pancreas receives blood chiefly from the splenic artery through its pancreatic branches, and from the superior mesenteric and hepatic by the inferior and superior pancreaticoduodenal arteries, which form a loop running around, below, and to the right of its head. The blood is returned into the portal vein by means of the splenic and superior mesenteric veins.

Lymphatics.—The lymphatics terminate in numerous glands which lie near the root of the superior mesenteric artery, above and below the neck of the pancreas. All the lymphatics drain ultimately into the celiac glands.

FIG. 966.—DIAGRAM SHOWING THE RELATIONS OF THE PANCREAS TO THE PRIMITIVE MESENTERY. (Poirier-Charpy.)



Nerves.—These are branches of the celiac plexus which accompany the arteries entering the gland. The main part of the celiac plexus lies behind the gland.

Minute anatomy.—In many respects, the pancreas resembles the salivary glands in structure, hence its German name 'Bauchspeicheldrüse' ('abdominal salivary gland'). The gland proper is racemose (or tubuloracemose) in structure. The thin-walled intercalary ducts, often invaginated to form centroacinar cells, are characteristic. The lobules are very loosely joined by areolar tissue, and there is no distinct fibrous capsule around the gland. The most important of the distinctive characters of the pancreas is the presence throughout the gland of numerous small interlobular cell-masses of varied form and size—the *islets of Langerhans* (fig. 967). These have no ducts, but are richly supplied with blood-vessels. They are ductless glands of great importance in sugar metabolism, and their removal or disease produces diabetes. While derived embryologically from the same entodermal anlage which gives rise to the pancreas gland proper, they apparently have no direct connections with it in the adult.

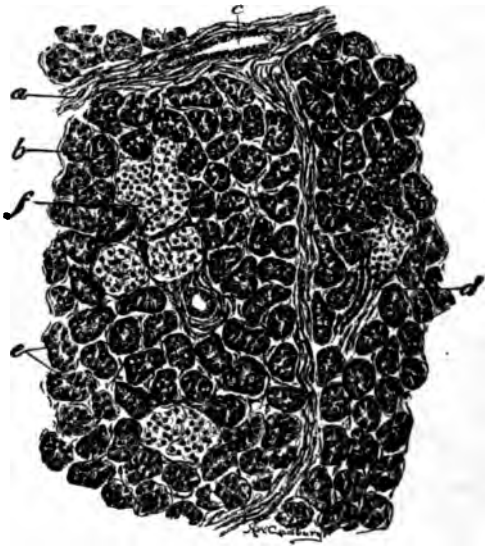
Development of the pancreas.—The earlier stages of development of the pancreas are described in Section I, p. 47. Of the adult gland, only the lower portion of the head is derived from the primitive ventral anlage, although the duct of the latter drains nearly the entire adult gland. The upper part of the head of the pancreas, and all of the body and tail are derived from the dorsal anlage; although most of its duct joins with the duct of Wirsung to form the main pancreatic duct, only a small part persisting as the accessory duct of Santorini.

During the early stages in the development of the pancreas the entodermal buds from which its forms grow into the mesoduodenum, and later the dorsal mesogastrium. With the rotation of the stomach and the consequent change in the position of the mesogastrium and its partial fusion with the abdominal wall (see *general morphogenesis*, p. 1173), the pancreas assumes a retroperitoneal position. This is illustrated by fig. 966. The head of the pancreas is involved in the rotation of the primitive intestinal loop around the superior mesenteric artery. This

accounts for the position and the hook-like form of the processus uncinatus. Following this rotation, the duodenum and the head of the pancreas become pressed backward against the posterior abdominal wall, where they become adherent, with fusion and obliteration of the primitive peritoneum. The body of the pancreas, extending into the dorsal mesogastrium (fig. 915), is similarly caught in the pouch-like downgrowth of the latter to form the bursa omentalis (lesser sac), and is thereby carried over to the left side. When the posterior layer of the primitive bursa fold becomes fused with the posterior abdominal wall, the enclosed pancreas is likewise fixed and becomes retroperitoneal. Of these obliterated peritoneal layers of the embryo, only certain layers of fascia remain as their representatives in the adult. From the lower aspect of the pancreas downward, the posterior layer of the bursa fold becomes fused with the transverse mesocolon, so that in the adult the latter appears to arise from the anterior border of the pancreas (fig. 922).

Variations.—Aside from minor fluctuations in size and form, the variations of the pancreas are chiefly congenital and of embryonic origin. Cases of *accessory or supernumerary pancreas* are not rare. They are usually of small size and have separate ducts. They may occur along the wall of the duodenum, or even in the stomach or jejunum. They are perhaps in some way connected with the numerous intestinal diverticula which occur in the embryo. *Divided pancreas*

FIG. 967.—SECTION OF HUMAN PANCREAS, MAGNIFIED, SHOWING SEVERAL ISLETS OF LANGERHANS. (Radasch.) *a*, Interlobular connective tissue, containing an interlobular duct, *c*. *b*, Capillary. *d*, Interlobular duct. *e*, Alveoli. *f*, Islet of Langerhans.



differ from the accessory in that a mass of the pancreas becomes separated from the main gland, connected only by a duct. This occurs oftenest in the region of the tail (sometimes extending into the spleen) or of the processus uncinatus, forming what is termed a 'lesser pancreas.' Sometimes a ring of glandular tissue from the head of the pancreas surrounds the descending duodenum, forming an *annular pancreas*. Variations in the *direction* of the body are numerous; it may be horizontal, ascending or bent in various ways. These are doubtless congenital variations, as similar types have been described in the fetus (Jackson). It has been experimentally demonstrated that varying degrees of distention of the stomach and intestines affect profoundly the *form of the body* of the pancreas. When the stomach alone is distended, the pancreas is flattened anteroposteriorly, the inferior surface being practically obliterated. When *both* stomach and intestines are distended, the pancreas is flattened from above downward, and extends forward like a shelf, the posterior surface being much reduced (Jackson). Numerous variations in the *ducts* are easily understood from their complicated development. The accessory duct (of Santorini) is in the fetus as large as the main duct (of Wirsung), the preponderance of the latter being established later. The accessory duct in the adult may be larger than usual, and retain its primitive drainage, or even drain the entire gland in rare cases where the duct of Wirsung is absent. Or the accessory duct may be rudimentary or (rarely) absent. Similar variations occur in the main duct of Wirsung. Rarely the pancreas may open into the duodenum by three ducts, probably representing three embryonic anlages. Abnormalities of the pancreas are often associated with duodenal diverticula.

Comparative.—The pancreas, like the liver, is constant throughout the vertebrates. It always arises by budding off from the endodermal epithelium of the intestine, closely associated with the liver. There is typically a triple anlage (rarely multiple, which is perhaps the ancestral type), with one dorsal and two ventral outgrowths. These fuse and form the adult pancreas in a variety of ways. In many of the fishes, the pancreas is very small, diffuse and inconspicuous, sometimes embedded in the liver or intestinal wall. Of the three primitive ducts, usually only two persist (as in man), but often only one, or all three (in birds). All three types occur in mammals. The islets of Langerhans arise from the epithelial pancreas anlage, and ap-

pear to be constantly present, even in the lowest vertebrates. Laguesse even considers that phylogenetically they form the most primitive part of the pancreas, but this is doubtful.

SECTION XI

THE RESPIRATORY SYSTEM

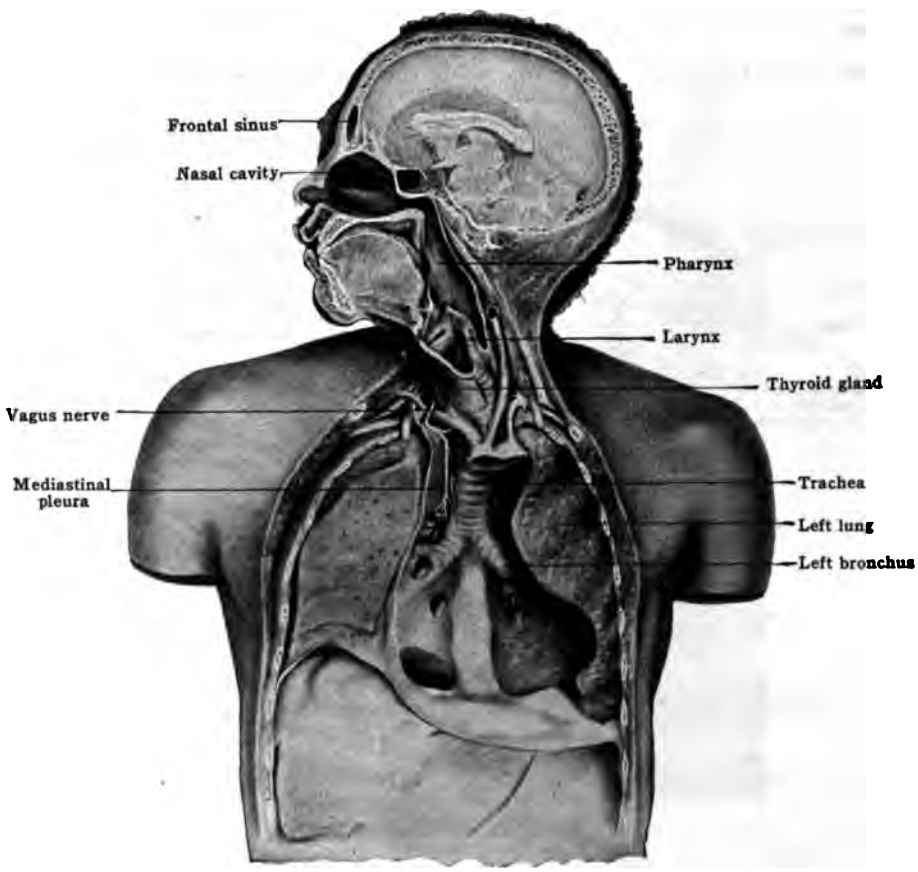
REVISED FOR THE SIXTH EDITION

BY J. PARSONS SCHAEFFER, M.D., PH.D.

PROFESSOR OF ANATOMY AND DIRECTOR OF THE DANIEL BAUGH INSTITUTE OF ANATOMY OF THE JEFFERSON MEDICAL COLLEGE

RESPIRATION in one form or another is one of the basic characteristics of living things It consists essentially in the absorption by the organism of oxygen and the discharge of a metabolic waste-product, carbon dioxide. The lungs in air-breathing vertebrates are eminently the seat of the interchange of these gases between the body and the air.

FIG. 968.—DISSECTION OF A MALE NEGRO, AGE 43 YEARS, TO SHOW THE ORGANS OF RESPIRATION IN SITU.



Among unicellular animals the oxygen is taken up directly from the medium—water or air—in which they live, and the carbon dioxide given off into it. With the cells which make up the body of higher animals the principle is the same, but the interchange of gases is indirect. The blood stands as an intermediate element between the cells of the body and the medium inhabited

pharynx and mouth in connection with alimentation, the several portion
nose functioning in the sense of smell. (For the description of the mou
pharynx see Section X; for the olfactory organ see Section IX.)

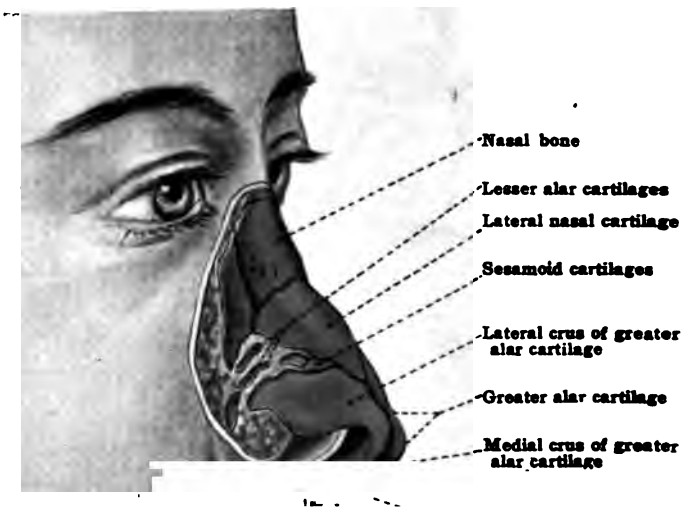
The organs of circulation are always adapted to the form of the respiratory appar
among all higher animals a connection is established between heart and lungs by the pu
artery, which carries venous blood to the latter, and by the pulmonary veins, whicl
arterial blood from the lungs to the heart, whence the aorta takes it into the general cir

In their origin and development, the respiratory organs are closely associated
differentiated from the beginnings of the digestive apparatus. Thus the processes of t
development of the nasal cavity and mouth are interdependent; the origin of the gre
of the larynx, the trachea and lungs is by outgrowth of the entodermal canal.

THE NOSE

The nose will here be described under three main heads as follows:
external nose; B, the internal nose or nasal cavity; C, the paranasal or ac
sinuses.

FIG. 969.—THE CARTILAGE OF THE EXTERNAL NOSE AS DISPLAYED (PROFILE VIEW)
THE REMOVAL OF THE SKIN AND MUSCLES. (Schaeffer.)

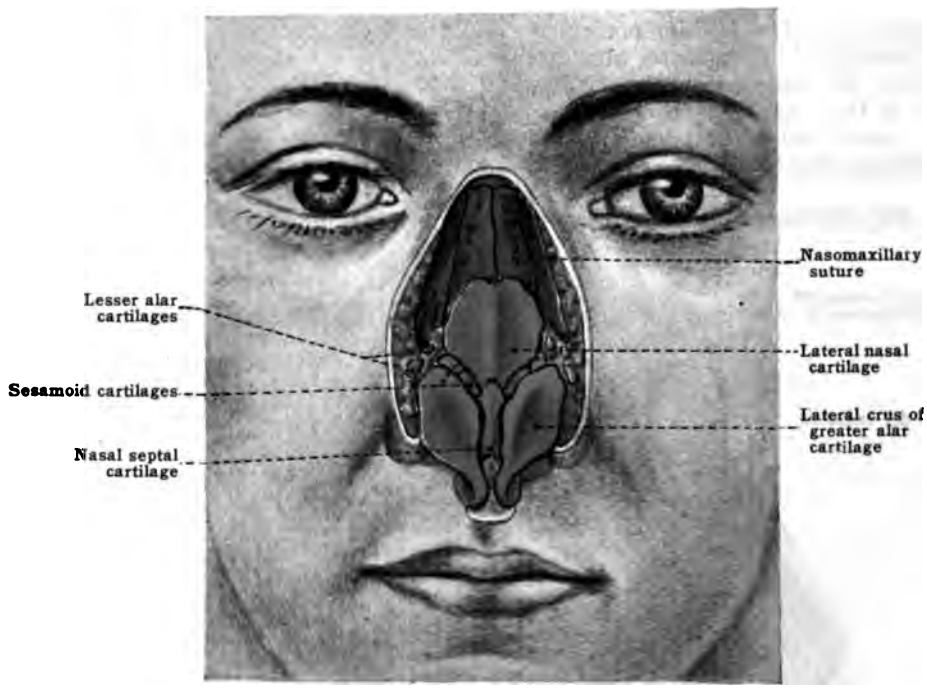


is a rounded ventral border, the **dorsum** of the nose [dorsum nasi], which may be either straight, convex, or concave, and which ends inferiorly at the **apex** of the nose [apex nasi]—the latter either in line with the dorsum nasi, depressed or upturned. The superior part of the dorsum is known as the bridge. Inferiorly, overhanging the upper lip, is the **base** of the nose [basis nasi] which presents two orifices, the **nares** or nostrils, separated from one another by the movable part of the nasal septum [septum mobile nasi].

The **sides of the nose** [partes laterales nasi] slope from the dorsum laterally and posteriorly, and below terminate on each side in the **margin** of the nose [margo nasi]; posteriorly and inferiorly the sides are expanded and more convex, forming the **alæ nasi.** Each of these is separated from the rest of the lateral surface by a sulcus, and the inferior free margin of each bounds a naris laterally.

Three types of nose, distinguished by differences in the proportion of breadth and length, are shown by the cephalometric nasal index $\left(\frac{\text{greatest breadth} \times 100}{\text{greatest length}}\right)$: the leptorrhine or long, high nose; the platyrrhine or short, low nose; the mesorrhine, a form intermediate between the other two. The leptorrhine type (index below 70) prevails among white races, the platyrrhine (index above 85) in the black peoples, and the mesorrhine (index between 70 and 85) in the red and yellow races. Minor variations in the morphology or shape of the external nose are numerous and of little significance; they represent individual and family characteristics.

FIG. 970.—THE CARTILAGES OF THE EXTERNAL NOSE AS DISPLAYED (FRONTAL VIEW) AFTER THE REMOVAL OF THE SKIN AND MUSCLES. (Schaeffer.)

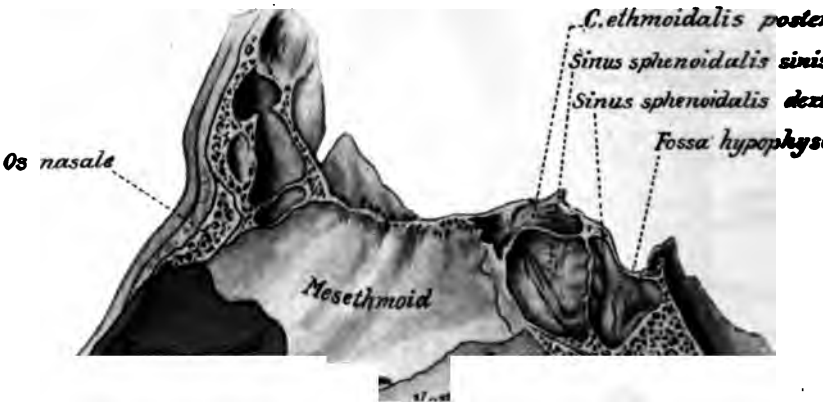


The framework of the external nose is formed partly of bone and partly of hyaline cartilage. The bones, which form only the smaller superior part, are the two nasal bones and the frontal processes and anterior nasal spines of the two maxillæ (pp. 155, 158).

The nasal cartilages [cartilagines nasi] (figs. 969–971) are located about the piriform aperture and constitute the larger part of the nasal framework. There are five principal cartilages: superiorly, the two *lateral nasal cartilages*; inferiorly the two *greater alar cartilages*, and the single median *nasal septal cartilage.* Besides these there are the *lesser alar cartilages*, the *sesamoid cartilages*, and the *vomeronasal cartilages* of Jacobson. The **lateral nasal cartilages** are triangular and nearly flat lateral expansions of the septal cartilage, placed one on each side of the nose just inferior to the nasal bone. Each presents an ental (deep) and an ectal (superficial) surface and three margins. The medial margin is continuous in its superior third with the anterior margin of the septal cartilage, and

the septum. The inferior margin is connected by fibrous tissue to the alar cartilage. The **greater alar cartilages** [cartilagines alares majores], in form, are situated one on each side of the apex of the nose (figs. 96 Each is thin, pliant, curved, and so folded that it forms a **medial and** crus, which bound and tend to hold open each naris. **The medial cr** mediale] is loosely attached to its fellow of the opposite side, **the two bei**

FIG. 972.—A DISSECTION SHOWING THE OSSEOUS AND CARTILAGINOUS SEPTUM OF TI
(Schaeffer.)



The angle formed by the crura (angulis pinnalis) varies with the shape of the nose; it averages 30°. The greater and lesser alar cartilages together form an incomplete ring around the naris.

A variable number of small cartilages, **lesser alar cartilages** [cartilagines alares minores] are found in the fibrous tissue of the ala, and in the interval between each greater alar and lateral cartilage occur one or more small plates, **sesamoid cartilages** [cartilagines sesamoideæ] (figs. 969, 970). Occasionally a posterior extension of the lateral crus of the greater alar cartilage replaces in part or in whole the lesser alar cartilages.

The **cartilaginous portion of the nasal septum** is formed by the septal cartilage, the vomeronasal cartilages and the medial crura of the greater alar cartilages (described above).

The **septal cartilage** [cartilago septi nasi] (fig. 972) forms the anterior part of the septum. It is quadrilateral in shape and fits into the triangular interval of the bony septum. Its anterosuperior margin in its upper part meets the inter-

nasal suture. Inferior to the nasal bone it presents a shallow groove which gradually narrows toward the tip of the nose, and whose borders are continuous superiorly with the lateral nasal cartilages, but are separated from their inferior two-thirds by a narrow slit. The most inferior part of this margin of the septal cartilage is placed between the greater alar cartilages. The anteroinferior margin extends backward from the rounded anterior angle to the anterior nasal spine. Inferiorly it is attached to the medial crus of the greater alar cartilage and to the mobile nasal septum. The posterosuperior margin is attached to the perpendicular plate of the ethmoid, and the posteroinferior margin joins the vomer and the anterior part of the nasal crest of the maxilla, the cartilage broadening out to obtain a wide though lax attachment to the nasal spine.

The *shape and size* of the septal cartilage varies with the extent of the ossification of the bony septum. Posteriorly the septal cartilage extends variously between the vomer and the perpendicular lamina of the ethmoid, thus forming the **sphenoidal process of the septal cartilage**. Indeed, the latter may be sufficiently elongated to reach the sphenoid bone—especially in children—and very frequently is the seat of a ridge-like horizontal projection into one or the other nasal fossa, causing septal asymmetry.

The **vomeronasal cartilages** [cartilagines vomeronasales, Jacobsoni] (fig. 972) are two narrow longitudinal strips, 7 to 15 mm. in length, which lie along the anterior portion of the inferior border of the septal cartilage. In this position the vomeronasal cartilages are attached to the vomer posteriorly and to the maxilla and the septal cartilage anteriorly. The vomeronasal

cartilages are not always differentiated from the septal cartilage. In man these cartilages reach their maximum development in the embryo. They are, however, always most conspicuous in animals in which the vomeronasal organ is well developed, forming a protecting and supporting framework for the organ.

Muscles.—The muscles of the external nose are grouped according to function as dilators and contractors, the latter being comparatively feeble in their action. They are described on p. 369.

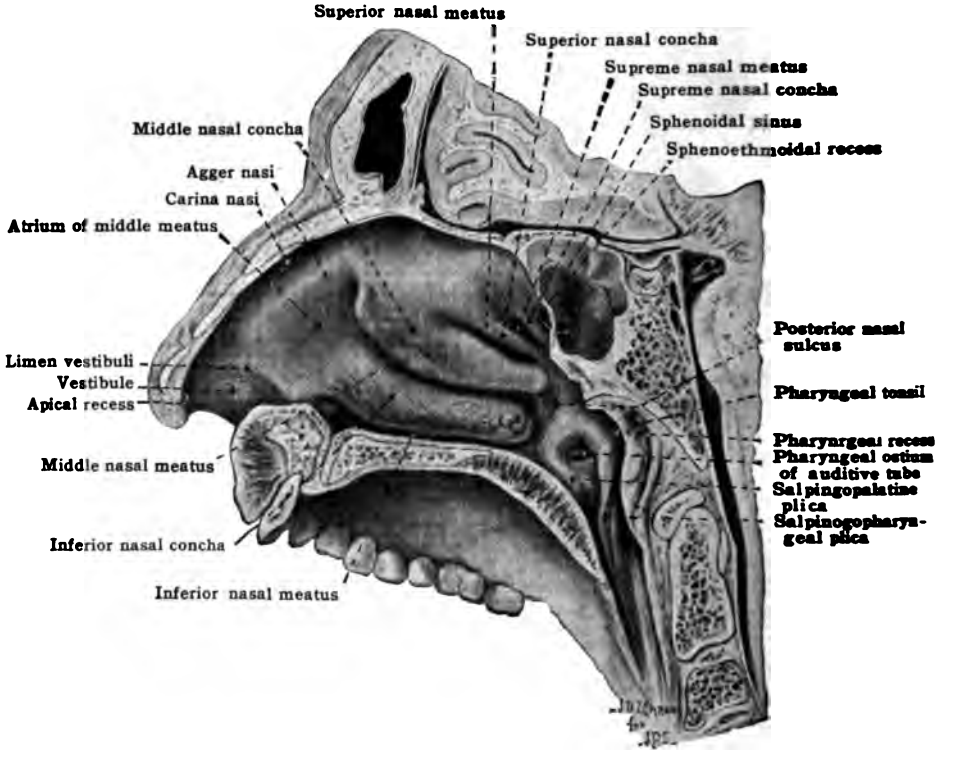
Skin.—The skin covering the external nose is thin and freely movable upon the subjacent parts, except at the tip and over the cartilages, where it is much thicker, more adherent, and furnished with numerous exceptionally large sebaceous glands. At the nares it is reflected into the nasal cavity, where it passes into the mucous membrane. The hairs on the skin of the nose are very fine, except in the nares, where they may be strongly developed.

Vessels and nerves.—The arteries of the external nose are derived from the external maxillary (facial) artery (pp. 582 and 583), the ophthalmic artery (p. 595), and the infraorbital artery (p. 590). The veins terminate in the anterior facial vein and the ophthalmic vein (p. 692). The lymphatics pass to the submaxillary and parotid lymphatic nodes (p. 742). The motor nerves are branches of the facial (p. 978). The sensory nerves are derived from the trigeminal through the frontal and nasociliary branches of the ophthalmic (p. 970) and infraorbital branch of the maxillary (p. 972).

THE INTERNAL NOSE

The **internal nose** consists of the nasal cavity and ancillary structures. The general **nasal cavity** [cavum nasi] is the roomy space situated between the floor of the cranium and the roof of the mouth, extending anteriorly into the external nose and posteriorly to the nasal part of the pharynx. The cavity is divided by a

FIG. 974.—LATERAL WALL OF THE RIGHT NASAL FOSSA AND THE NASAL PHARYNX.



median **septum** [septum nasi] into two more or less symmetrical halves—the **nasal fossæ** [fossæ nasales]. Moreover, the fossæ are further incompletely divided into **nasal meatuses** [meatus nasi] by the **nasal conchæ or turbinates** [conchæ nasales], and are extended into neighboring bones by the **paranasal** or accessory **sinuses** [sinus paranasales]. The nasal fossæ communicate freely with the exterior through the **nares** (anterior nares) and with the nasopharynx dorsally through the **choanæ** (posterior nares). With the exception of the anterior portion of the nose, where the boundaries are completed by cartilages and membranes, the walls of the nasal cavity are almost wholly of bone as described in the section on OSTEOLOGY (pp. 115–117). The walls of the nasal cavity are covered

by periosteum and mucous membrane, the latter presenting important histological differences, leading to the division of the nasal cavity into **respiratory** and **olfactory** portions [regiones respiratoria et olfactoria]. The former, the lower and greater portion of the nasal cavity, has especially to do with the function of respiration and the latter, the extreme upper portion of the nasal cavity, is primarily concerned with the function of smell and is, strictly speaking, the **peripheral olfactory organ** (see Section IX for the olfactory organ proper).

The nasal fossæ.—The paired nasal fossæ are roughly triangular in the frontal or coronal plane (fig. 975). The narrow roof of each fossa may be considered the apex of the triangle and the wider floor the base, the mesial or septal wall, normally even and approximately vertical, meeting the floor at nearly a right angle. The lateral wall, the hypotenuse of the triangle, is sloping and configured by the nasal conchæ and meatuses and the encroaching paranasal air sinuses. In sagittal section (fig. 974) each nasal fossa is quadrangular in shape, the roof being more or less parallel with the floor, the anterior side conforming to the profile of the external nose and forming with the floor at the naris an acute angle, and the posterior side passing from the anterior surface of the body of the sphenoid bone, through the choana of the respective side to the juncture between the hard and soft palates. The posterior limit of the nasal fossa is indicated on the lateral nasal wall by the *posterior nasal sulcus* (fig. 974).

While there is considerable variation in the dimensions of the nasal fossæ, the following may be taken as representative dimensions: The greatest sagittal diameter, measured from the most prominent part of the naris along the floor of the nasal fossa to the posterior border of the hard palate, is 74 mm.; the greatest sagittal diameter, measured along the roof of the fossa, is 35 mm. or less; the greatest vertical diameter, measured from the cribriform plate to the nasal floor, is from 40 to 45 mm.; the width of the roof 3 mm. or less; the width of the floor, measured at the greatest lateral expansion of the inferior meatus, varies from 12 to 23 mm.

The vestibules [vestibula nasi].—The vestibules are the dilated passage-ways leading in from the nares and may be considered antechambers to the nasal fossæ, corresponding more or less to the cartilaginous portion of the external nose and supported by the medial and lateral plates of the greater alar cartilages and adjacent portions of the nasal septum and integument.

The extension of the vestibule into the tip of the nose is often referred to as the *ventricle* of the vestibule, or the *recessus apicis* (fig. 974). On the lateral wall the vestibule is marked off from the rest of the nasal fossa by a distinct ridge, the *limen nasi* (or limen vestibuli), corresponding to the superior margin of the greater alar cartilage (fig. 974). At the limen nasi the skin lining the vestibule suffers a transition into the mucous membrane lining the nasal fossa proper. The skin lining the vestibule is beset with large hairs called vibrissæ, and contains sudoriferous and sebaceous glands.

The choanæ (posterior nares).—These are the paired communicating passage-ways between the nasal fossæ and the nasal pharynx (fig. 974). The apertures are oval in form with the vertical diameter greater than the transverse, the comparison being shown by the *choanal index*, $\frac{\text{transverse diameter} \times 100}{\text{vertical diameter}}$. They have definite osseous boundaries and are lined with mucoperiosteum continued from the nasal fossæ into the nasal pharynx. The choanæ are located at either side of the free posterior border of the nasal septum and are limited above by the body of the sphenoid and the alæ of the vomer, below by the line of junction of the hard and soft palates, laterally by the medial plates of the pterygoid processes. The osseous boundaries of the choanæ cause the apertures to stand permanently open and free for the transmission of air.

The transverse diameter of each choana varies from 12 to 17 mm. at the floor and from 7 to 10 mm. at the roof. The vertical diameter varies from 24 to 33 mm. The choanal index for the male averages approximately 61 and for the female 64.5. Posterior rhinoscopic examination reveals the choanæ, the nasopharyngeal meatus, the posterior extremities of the nasal conchæ and of the nasal meatuses beneath them.

The nasal septum (fig. 972).—The medial wall of the nasal fossa is formed by the nasal septum (fig. 972). It is supported posteriorly by a framework composed of osseous elements [septum osseum], anteriorly by cartilaginous elements (septum cartilagineum) and anteroinferiorly by integument and subcutaneous tela [septum membranaceum; septum mobile nasi]. The nasal mucous membrane covers all portions of both sides of the septum, save the vestibular part which is invested by integument continued through the nares from the exterior.

attached border of the inferior concha and below by the floor of the nose. It measures from 4.5 to 5.8 cm. in length, beginning variously from 2.5 to 3.7 cm. behind the tip of the nose. The inferior meatus is narrow anteriorly, expanding rapidly in width and height, to narrow again toward the choana.

The *ostium of the nasolacrimal duct* (fig. 976) is located on the anterior portion of the lateral wall of the inferior meatus, from 15 to 20 mm. behind the limen nasi and from 30 to 40 m. behind the naris. It is located either at the highest point of the inferior meatus or at varying distances (2 to 10 mm.) below this point. The ostium is usually a single opening, but duplication or triplication may occur. The aperture may be either located close to the attached border of the inferior concha, wide-mouthed, standing permanently open, or located lower, slit-like, collapsed and guarded by a fold of mucous membrane, the so-called valve of Hasner [plica lacrimalis, Hasneri].

The **middle nasal concha** [concha nasalis media] (figs. 974–976) is relatively large, hanging valve-like over the middle nasal meatus. It hides or operculates a number of secondary conchæ and furrows in the middle meatus. The contained osseous lamina, a part of the ethmoid bone, is covered by a thick mucous membrane, erectile in character.

FIG. 977.—ANATOMIC TYPE IN WHICH THE NASOFRONTAL DUCT AND THE INFUNDIBULUM ETHMOIDALE ARE CONTINUOUS. (After J. Parsons Schaeffer.)

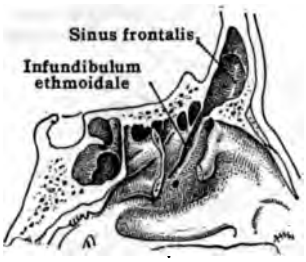


FIG. 978.—ANATOMIC TYPE IN WHICH TWO FRONTAL SINUSES ARE PRESENT, BOTH DISCONTINUOUS WITH THE INFUNDIBULUM ETHMOIDALE. (After J. Parsons Schaeffer.)

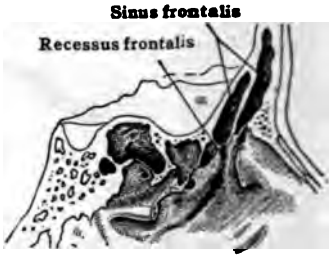


The free border of the concha presents a marked genu, giving rise to a short vertical or ascending limb and a larger horizontal or descending limb. The genu very commonly enlarges by the formation of a lobule, surmounted by a secondary nodule. Equally common is the presence of ethmoidal cells in the body of the concha media (see PARANASAL SINUSES).

The **middle nasal meatus** [meatus nasi medius] (figs. 974–976) is the most complex and important of the nasal meatuses. It is divided into an *ascending* and a *descending* ramus; the latter, spacious and arched, conforms to the contour of the middle and inferior conchæ; the former, often called the **frontal recess,** is much less roomy and is merely an extension frontalward of the middle meatus proper. On removing or turning upward the middle nasal concha one discloses on the lateral wall of the decending ramus of the middle meatus immediately below the attached border of the middle concha a conspicuous bleb-like structure—the **ethmoidal bulla,** and below the latter a sharp, crescentic lamella—the **uncinate process.** Between the free border of the uncinate process and the ethmoidal bulla is a crescentic cleft from 15 to 20 mm. long—the **semilunar hiatus,** which in turn leads from the middle nasal meatus into a crescentic groove of variable depth (from 1–12 mm.), the **ethmoidal infundibulum.**

The ethmoidal infundibulum usually ends blindly frontalward by forming one or more anterior ethmoidal air-cells (infundibular cells) (fig. 976) and ends posteriorly either in a pocket or merges gradually with the middle meatus. Occasionally it is directly continuous with the nasofrontal duct (infundibulum of the frontal sinus) or in the absence of the latter with the frontal sinus proper (fig. 977). The ethmoidal infundibulum contains in its depth the ostia or apertures of the infundibular group of anterior ethmoidal cells and the ostium of the maxillary sinus (ostium maxillare).

The groove or furrow located between the ethmoidal bulla and the attached border of the middle nasal concha is the *suprabullar furrow or recess.* It contains the apertures or ostia of most of those anterior ethmoidal cells sometimes classed as middle ethmoidal cells (bullar group of anterior ethmoidal cells).

The lateral wall of the middle nasal meatus between the attached border of the uncinate process and the inferior nasal concha is at places wholly membranous, and presents the acces-

ory maxillary ostium between the middle meatus and the maxillary sinus in from 25 to 40 per cent. of cases.

The anterosuperior portion of the middle nasal meatus, i. e., the vertical or ascending ramus (frontal recess) is a pouch-like extension communicating with the frontal group of anterior ethmoidal cells (fig. 976) and the frontal sinus. Occasionally the ethmoidal infundibulum and the duct of the frontal sinus or the frontal sinus proper are continuous channels and groove the lateral wall of the frontal recess (fig. 977); but usually the ethmoidal infundibulum and the nasofrontal duct are anatomically discontinuous channels (figs. 976, 978).

The **superior nasal concha** [concha nasalis superior] (fig. 974) is a short thin lamina of bone which projects from the lateral ethmoidal mass and slightly overhangs the superior nasal meatus. The mucous membrane covering the concha is thinner and less erectile in character than that of the middle and inferior conchæ. The **superior nasal meatus** [meatus nasi superior] (figs. 974, 976) is a narrow channel-like depression below the related concha and approximately half the length of the middle nasal meatus. Not infrequently an accessory concha molds the lateral wall of the superior meatus and divides the latter into superior and inferior recesses. The latter recesses and the anterior end of the superior meatus receive the ostia or apertures of the posterior ethmoidal cells.

The **supreme nasal concha** [concha nasalis suprema] (figs. 974, 976), found bilaterally or unilaterally in approximately 60 per cent. of bodies, is the smallest of the conchæ. It projects only slightly medialward from the posterosuperior part of the lateral nasal wall, overhanging the **supreme nasal meatus.** The latter, found in a corresponding number of bodies, is a shallow, short furrow which (in about 75 per cent. of cases) contains the ostium or aperture of a posterior ethmoidal cell (fig. 976).

Immediately above and behind the supreme concha, or the superior concha in those cases in which the former is wanting, is the **sphenoethmoidal recess** (figs. 974, 976). The latter lies in the angle between the ethmoid and the anterior surface of the body of the sphenoid bone. Posteriorly the recess receives the ostium of the sphenoidal sinus (figs. 974, 976).

The roof of the nasal fossa.—The roof of the nasal fossa (fig. 974) may be considered as a cranially arched structure with the cribriform plate forming the horizontal middle portion; the body of the sphenoid bone together with the wing of the vomer and the sphenoidal process of the palate bone, the curved posterior portion; and the frontal and nasal bones, the curved anterior portion. The entire framework is covered by nasal mucous membrane.

Anteriorly the roof of the fossa is very narrow, but it gradually widens as the choanal aperture is approached. The greatest breadth of the cribriform plate (roof proper) is approximately 5 mm. Cranially the cribriform plate supports the olfactory lobe of the brain (fig. 975) and is perforated by foramina for the passage of the olfactory nerves, etc. Anteriorly, close to the crista galli, is a longitudinal fissure (the nasal fissure) for the transmission of the anterior ethmoidal branch of the nasociliary nerve and the anterior ethmoidal vessels.

The floor of the nasal fossa.—The osseous framework of the nasal floor (figs. 974, 975) is formed by the palatal processes of the maxillæ and the horizontal processes of the palate bones. Mucous membrane covers the framework. The floor of each nasal fossa is essentially horizontal in the sagittal plane, a distinct elevation appearing just inside the limen nasi, and concave in the frontal plane.

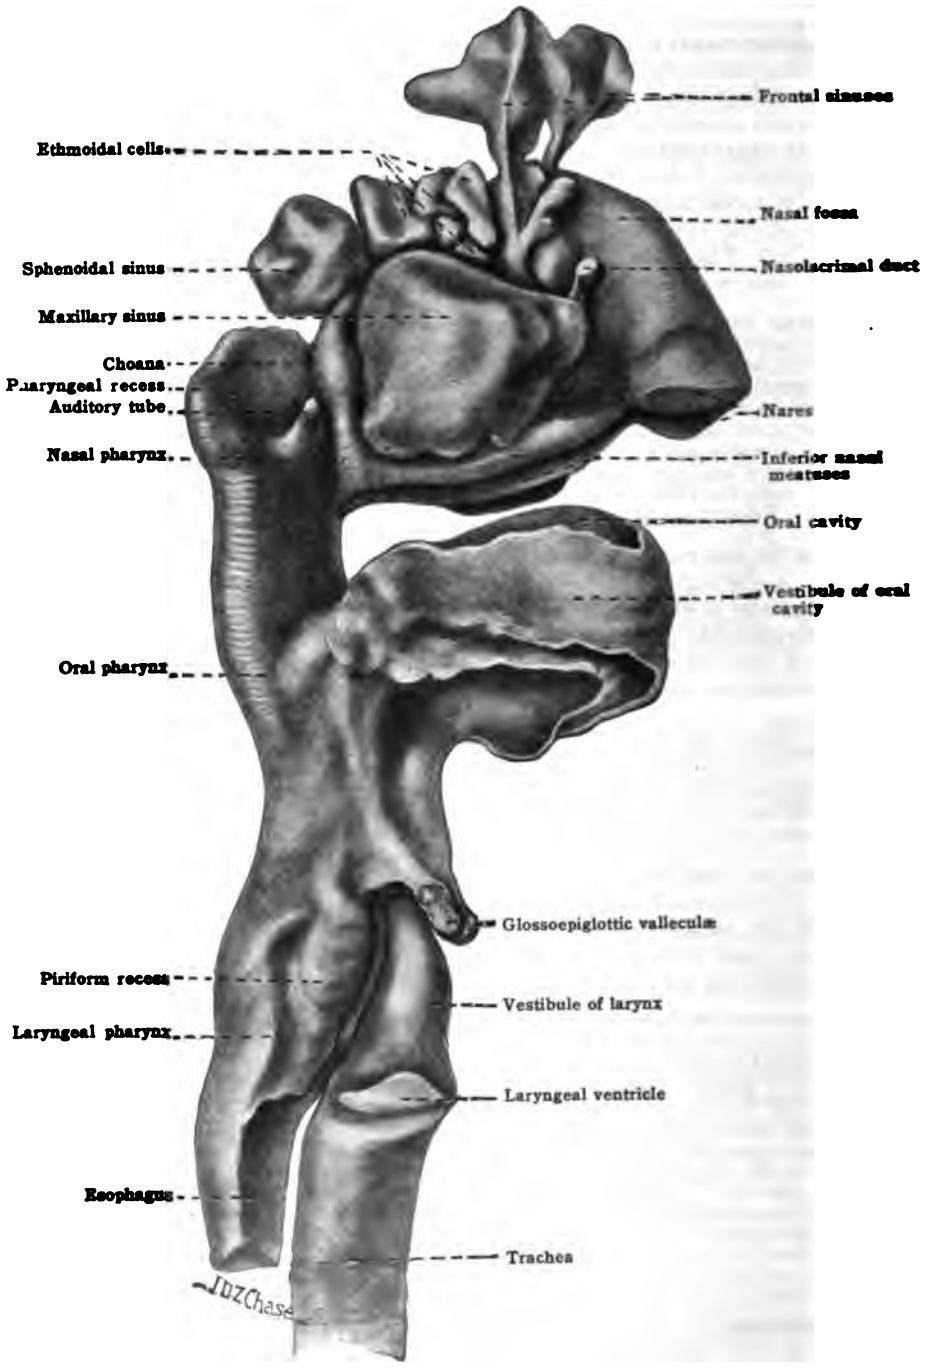
Approximately 2 cm. behind the inner margin of the nostril, each nasal fossa contains a slight depression in its floor which leads into a funnel-shaped tube of mucous membrane—the **nasopalatine canal** [canalis incisivus] or incisive canal of Stenson, located in the anterior palatine canal in the hard palate. The right and left nasopalatine canals may join and pass through the stem of the Y-shaped anterior palatine canal or incisive foramen as a common channel; however, more commonly each retains its individuality (Schæffer). The canals end in the roof of the mouth at the side of the palatine papilla. In the adult the lumina of the nasopalatine canals are usually obliterated by impervious cords of epithelial cells, but occasionally remain open (fig. 974). They are the remnants of the wide embryonic communication [ductus incisivus] between the nasal and oral cavities, which persist throughout life in many animals.

PARANASAL SINUSES

The **paranasal** (or accessory) **sinuses** [sinus paranasales] begin from the third to the fourth fetal month as evaginations from the mucosa of the nasal meatuses proper or their secondary furrows. However, the sphenoidal sinus is primarily a constriction from the posterosuperior region of the nasal fossa and is, therefore, not an outgrowth from a nasal meatus. The evaginating sacs wander into neighboring portions of the nasal walls, and by a joint growth of the sacs and an absorption of bone ultimately pneumatize large portions of the ethmoid, frontal,

maxillary and sphenoid bones in the formation of the *ethmoid cells*, *frontal sinus*, *maxillary sinus*, and *sphenoidal sinus*. respectively.

FIG. 979.—CAST OF THE NASAL FOSSÆ, PARANASAL SINUSES, ORAL CAVITY, PHARYNX AND LARYNX. Lateral view. After a cast by J. P. S. and C. H. H. in the Daniel Baugh Institute of Anatomy of the Jefferson Medical College.



Although many of the paranasal sinuses grow far from the point of initial evagination, the initial or primary points of outgrowth persist in the adult as the ostia or apertures of communication between the sinuses and the nasal fossa. The location, form and relations of the paranasal sinuses as found in the dried skull (in which the ostia may be considerably larger) have been briefly described in the section on OSTEOLOGY.

The maxillary sinus [sinus maxillaris] (antrum of Highmore).—The adult maxillary sinus is located in the body of the maxilla and is, as a rule, the largest of the pneumatic paranasal chambers (figs. 975, 979). It follows in the main the shape of the body of the maxilla and may be described as having a roof, a floor, and three walls. The *medial wall* or base forms part of the lateral wall of the nasal cavity, and the *apex* extends into the zygomatic process of the maxilla, or beyond it into the maxillary border of the zygomatic bone. The *anterior wall* of the maxillary sinus corresponds to the anterior or facial wall of the maxilla; the *posterior wall* to the infratemporal surface of the maxilla; the *roof* to the orbital surface of the maxilla, and the *floor* to the alveolar process of the maxilla. A thin mucous membrane, continuous through the aperture of the sinus with that lining the nasal fossa, lines the maxillary sinus throughout.

In very many instances the maxillary sinus is not a simple pneumatic cavity or chamber, but is incompletely divided into subcompartments and recesses by osseous and membranous septa. Sometimes a posterior ethmoidal cell grows into the body of the maxilla behind the maxillary sinus proper, the condition simulating a division of the maxillary sinus into two complete and separate compartments.

The number of teeth that bear direct relations to the floor of the maxillary sinus varies with the degree of excavation of the alveolar process of the maxilla. The teeth most constantly in intimate relationship to the maxillary sinus are the three molars and the second premolar; or, when the sinus is small, the second and third molars only. The majority of maxillary sinuses have their floors at varying distances below the level of the floor of the nasal fossa.

The maxillary sinus communicates with the deep aspect of the posterior half of the infundibulum ethmoidale by means of an oval or elongated aperture or ostium, the **ostium maxillare.** The ostium is very disadvantageously placed as a drainage opening, since it is located at the highest point in the medial wall of the cavity, and opens into the narrow infundibulum ethmoidale (described above). The ostium maxillare is sometimes double (fig. 975).

In more than one-third of specimens the maxillary sinus contains an additional aperture, the **ostium maxillare accessorium,** which communicates directly with the middle nasal meatus proper. The aperture is usually located between the posterior third of the processus uncinatus and the adjacent part of the attached border of the inferior nasal concha. It is more advantageously placed for drainage than is the constant aperture.

Measurements of 150 specimens of the adult maxillary sinus gave as the average the following (Schaeffer): posterosuperior diagonal, 38 mm.; anterosuperior diagonal, 38.5 mm.; superoinferior, 33 mm.; anteroposterior, 34 mm.; mediolateral, 23 mm. Increase in capacity of the maxillary sinus is not infrequently observed as the result of more extensive excavation of the bony processes of the maxilla, e. g., the alveolar, palatal, frontal and zygomatic. A lessened capacity may be due to unusually thick sinus walls, bulging sinusward of the facial and nasal walls, and the retention of certain teeth.

The frontal sinus [sinus frontalis].—The paired frontal sinuses (figs. 976, 979) are located between the outer and inner laminæ (tables) of the frontal bone and are extremely variable in size, shape and type (cf. pp. 131 and 1335). They develop variously as a direct extension of the whole frontal recess of the middle nasal meatus, from one or more anterior ethmoidal cells which have their points of origin in the furrows of the frontal recess, or occasionally from the anterior extremity of the ethmoidal infundibulum. The frontal sinuses are usually asymmetrical, one frequently encroaching markedly upon the confines of the other, with a corresponding displacement of the intervening septum [**septum sinuum frontalium**].

Seldom, indeed, are the frontal sinuses simple chambers, being more or less divided into subcompartments or recesses by incomplete bony partitions. Supernumerary frontal sinuses are extremely common, each with an independent connection with the nasal cavity. As many as six frontal sinuses have been observed in one skull. Rarely one or both sinuses are wholly wanting.

The typical frontal sinus may be said to be pyramidal, occupying the squama frontalis or vertical portion of the frontal bone. The pyramidal shape, however, of the sinus is very commonly greatly modified, by the extension of the cavity into the pars orbitalis of the frontal bone. Often it does not invade far into the vertical portion of the frontal bone, but grows extensively into the orbital portion. There may be a total absence in one or the other portion.

The frontal sinus usually communicates with the pouch-like **frontal recess** of the middle nasal meatus, either by means of a constricted canal, the **nasofrontal duct** (infundibulum of the frontal sinus), with proximal and distal **frontal ostia,** or by a fairly large direct single **frontal ostium** communicating between the frontal recess and the frontal sinus.

Occasionally the nasofrontal duct, or the frontal sinus proper in the absence of a duct, is directly continuous with the infundibulum ethmoidale (fig. 977). Usually, however, the infundibulum ethmoidale and the nasofrontal duct are discontinuous channels (figs. 976, 975). In approximately one-half of the latter cases the relationship is so intimate that secretions from the frontal sinus readily drain into the infundibulum ethmoidale, thence by way of the ostium maxillare into the sinus maxillaris. The efficiency of the nasofrontal duct as a drainage channel is in direct ratio to its length, diameter and directness. Often anterior ethmoidal cells encroach upon it, causing it to be constricted and sinuous in its course. Many frontal sinuses have no true nasofrontal duct, the sinus itself opening into the frontal recess by a direct single frontal ostium.

In a recent study of a large series of adult frontal sinuses average measurements were found as follows: height, 27.9 mm.; width, 23.25 mm.; depth, 19.25 mm. The combined volume of the right and left frontal sinus averaged 14 cc. (range 1–45 cc.). The frontal sinus is ethmoidal in topography before it is frontal.

One usually cannot be certain which of the potential rudiments are to develop into the frontal sinus until the latter half of the first year of postnatal life. By the end of the second year the frontal sinus has eroded into the vertical portion of the frontal bone, measuring 5 × 3 × 4 mm. and by the sixth year measures 8 × 4 × 6 mm.

The ethmoidal cells [cellulæ ethmoidales].—The ethmoidal air-cells (figs. 975, 976, 979) are primarily extensions or evaginations of the nasal mucous membrane from the middle, superior and supreme nasal meatuses, or from their secondary furrows and recesses. The ethmoidal cells by their growth ultimately honeycomb the lateral masses of the ethmoid bone and collectively form the paired *ethmoidal labyrinths* which occupy the space between the upper part of the nasal fossæ and the orbits.

Not infrequently the ethmoidal cells extend into certain of the nasal conchæ and the secondary folds of the related meatuses, forming the *conchal cells;* and into neighboring bones, forming *ethmofrontal, ethmomaxillary, ethmosphenoidal* and *ethmopalatine* cells. A very thin mucous membrane, directly continuous with that of the respiratory region of the related nasal meatuses, lines the cells. Not infrequently the osseous boundaries are deficient.

The ethmoidal cells are divided into two primary groups, the anterior and the posterior ethmoidal cells. The **anterior group,** from two to eight in number, have their ostia in communication with various parts of the middle nasal meatus. The anterior ethmoidal cells are subdivided into *secondary groups,* viz., the **frontal ethmoidal cells,** opening into the frontal recess of the middle meatus; the **infundibular ethmoidal cells,** opening into the ethmoidal infundibulum of the middle meatus; and the **bullar ethmoidal cells** (often called the middle ethmoidal cells), opening into the middle meatus, either upon or above the ethmoidal bulla, the latter being hollowed out by them (figs. 975, 976). The **posterior group,** from one to seven in number, have their ostia or apertures above the middle nasal concha and in communication with both the superior and supreme nasal meatuses.

The supreme meatus is found in about 60 per cent. of adult specimens and 75 per cent of these receive the ostium of a posterior ethmoidal cell. The superior meatus receives the apertures of posterior ethmoidal cells in practically all cases (fig. 976).

In a recent study, the number of cells composing the ethmoidal labyrinth was found to vary from 3 to 15. The fewer the cells, the larger are the individual cells, since the ethmoidal labyrinth occupies the entire ethmoidal field whether composed of few or many cells. In the newborn, the anterior group measures on the average 5 × 2 × 2 mm. and the posterior group 5 × 4 × 2 mm. In the adult the anterior group measures on the average 23.6 mm. in height, 22.6 mm. in length, and 11 mm. in width. The corresponding diameters of the posterior group are 20.8 mm., 20.5 mm. and 12 mm., respectively.

The sphenoidal sinus [sinus sphenoidalis].—The paired sphenoidal sinuses (figs. 976, 979) pneumatize the body of the sphenoid bone and not infrequently extend into the great wings, the pterygoid processes and the rostrum of the sphenoid and the basilar process of the occipital bone. Occasionally they may replace certain of the posterior ethmoidal cells, coming into immediate relationship with the maxillary sinus. The converse may occur in which one or more posterior ethmoidal cells may encroach upon the sphenoidal sinus. The sphenoidal sinuses vary greatly in size and shape and are usually asymmetrical, with corresponding asymmetry of the intervening **sphenoidal septum** [septum sinuum sphenoidalium].

Sphenoidal sinuses may be either very rudimentary or extremely large. The dimensions of the average sinus may be given as follows: height, 20 mm.; width, 18 mm.; length, 21 mm. Conforming with the variations in size, the capacity of the sphenoidal sinus varies from 0.5 cc. to 30 cc., with an approximate average of about 7.5 cc.

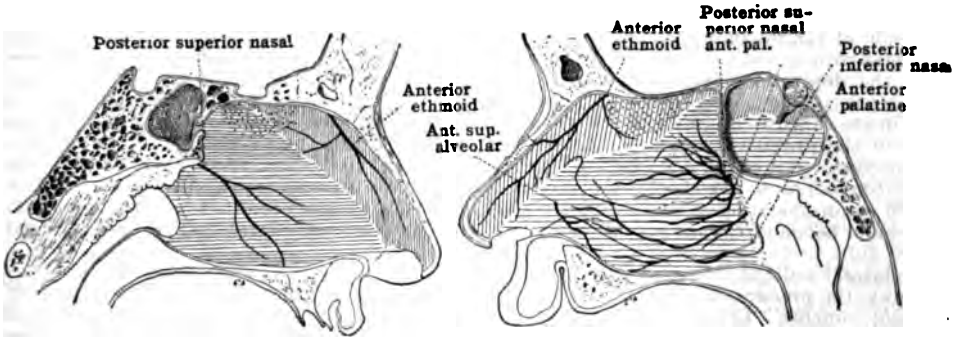
The sphenoidal sinus of each side communicates with the sphenoethmoidal recess of the nasal fossa by means of an aperture, the **sphenoidal ostium** [apertura sinus sphenoidalis]. The latter is large in the dried skull, but much reduced in the recent and living state by the respiratory mucous membrane.

The ostium sphenoidale is located in the anterior wall of the sphenoidal sinus from 3 to 20 mm. above the floor. It always opens into the posterior wall of the sphenoethmoidal recess above the uppermost nasal concha. The sphenoidal ostium is very disadvantageously placed as an efficient drainage aperture owing to its great distance from the floor of the sphenoidal sinus, averaging 14 mm.

The sphenoidal sinus arises primarily in relation with the posterior cupola of the cartilaginous nasal capsule, the wall of which gives the foundation for the sphenoidal turbinal or ossicle of Bertin. The posterior cupola or recess is, strictly speaking, the primitive sphenoidal sinus and is demonstrable as early as the fourth month of fetal life. It is only after the ossicle of Bertin fuses with the ethmoid bone, which occurs during the fourth year of infancy, that the sphenoidal sinus begins to excavate the body of the sphenoid. The average sphenoidal sinus of the term fetus has a capacity of from 6 to 8 cubic mm. By the second year the sphenoidal sinus averages 4 × 3.5 × 2 mm.; the fifth year 7 × 6.5 × 4.5 mm.; and by the ninth year 5 × 12 × 10 mm.

FIG. 980.—DIAGRAM OF THE DISTRIBUTION OF THE NERVES IN THE NASAL CAVITY. (Poirier and Charpy.)

The olfactory area is represented by dots.



Functions of the paranasal sinuses.—It is unlikely that the paranasal sinuses exert any influence upon vocalization and they supply an insignificant amount of moisture in the form of mucus to the nasal fossæ. The sinuses may, by lightening the ventral and facial part of the skull, aid in bringing about proper equipose of the head. There is some phylogenetic evidence that some of the paranasal sinuses at one time had to do with the olfactory function. However, with the marked reduction of the olfactory sense in man, the one conspicuous and probably dominant function remaining is that as an adjunct to respiration, particularly to aid in warming and humidifying the inspired air.

The mucous membrane of the nose [membrana mucosa nasi] completely lines the nasal cavity and inferiorly, at the limen nasi, blends with the skin covering the walls of the vestibule. Posteriorly it joins the mucous membrane of the pharynx and palate. It covers some of the openings which are seen in the bony walls; those apertures, however, which lead into the paranasal sinuses and into the nasolacrimal duct remain patent, although as already stated the bony openings are much reduced in size.

In the nasal cavity the bright rose-red vascular mucous membrane is tightly bound to the periosteum and perichondrium, and is covered with a ciliated columnar epithelium. Numerous large mucous **nasal glands** [glandulæ nasales] pour their more or less watery secretion over the entire surface. A very considerable venous plexus is found in many parts of the nasal mucosa. Over the inferior concha and to a less extent in the mucosa of the middle and superior conchæ, it forms the **cavernous plexuses** of the **conchæ** [plexus cavernosi concharum] contributing to build up about these bodies a true erectile tissue. The thickness which these glands and venous plexuses give to the mucous membrane of the conchæ causes the marked increase in size of these bodies over that of their bony supports. The region covered by the mucous membrane just described forms the greater part of the nasal cavity, and is known as the **respiratory region** [regio respiratoria]. The mucous membrane of a small area over the superior and supreme conchæ, a small portion of the middle concha and the adjacent septal wall (fig. 980) has a somewhat different structure. In this area the olfactory nerves are distributed, whence it is known as the **olfactory region** [regio olfactoria], and its mucous membrane, compared with that of the respiratory region, is less vascular, yellow or yellowish-brown in color, and covered by a non-ciliated epithelium. Its cells, specially modified, some of which are directly connected

with the olfactory nerve, form the **olfactory organ** [organon olfactus]. **Small mucous olfactory glands** [glandulæ olfactoriæ] occur in the region. The mucous membrane which lines the *paranasal sinuses* throughout is a continuation of the nasal mucosa; it is, however, paler, less vascular, somewhat thinner, and more loosely attached to the bones. **Mucous glands** are numerous.

Vessels and nerves.—The **arteries** of the nasal cavity are the **sphenopalatine** artery from the internal maxillary which, through its posterior lateral nasal branches, supplies a goodly portion of the nasal conchæ (p. 590), and through its posterior septal branches (**nasopalatine** artery) supplies the inferior and posterior portion of the nasal septum; the **anterior and posterior ethmoidal** arteries from the ophthalmic (p. 594) supply portions of both **medial and lateral nasal** walls; the descending palatine artery from the internal maxillary supplies small branches to the posterior portion of the nasal fossa and by its direct continuation (the **great palatine artery**) passes through the incisive foramen to the anterior portion of the floor of the **nasal fossa** (p. 590), and the superior labial branch of the external maxillary supplies the **vestibule** and adjacent parts. The **venous plexuses** of the mucous membrane are drained posteriorly by the sphenopalatine to join the pterygoid plexus, superiorly by the anterior and posterior ethmoidal veins to join the superior ophthalmic vein, and anteriorly by small branches to join the facial. The **lymphatics** form a well-developed plexus which is said to communicate indirectly, through the lymph-spaces surrounding the olfactory nerves, with the subdural and subarachnoid spaces. Posteriorly two or more well-developed trunks communicate with the **pharyngeal lymphatics**, and anteriorly the nasal lymphatics join with the lymphatics of the face. The **olfactory nerves** pass through the cribriform plate of the ethmoid bone and are distributed to the olfactory bulb (p. 962). The **trigeminal nerve** furnishes the following branches to the **nasal cavity**: branches from the nasociliary branch of the ophthalmic nerve; the posterior **superior and posterior inferior nasal**, the nasopalatine and the anterior palatine from the **sphenopalatine ganglion** (p. 995); the anterior superior alveolar from the infraorbital division of the **maxillary nerve** (p. 970). See also the terminal and vomeronasal nerves (p. 962).

The development of the nose.—The nasal cavity makes it appearance as a depression on either side of the median line, immediately above the oral fossa, with which the depressions are at first continuous. Later, by the fusion of the maxillary and medial **nasal processes** (see p. 16), the depressions or nasal pits are separated from the oral fossa. The **nasal pits** then establish a secondary connection with the roof of the primitive mouth-cavity by an attenuation and ultimate rupture (45-day embryo) of the bucconasal membranes of **Hochstetter** in the formation of the primitive choanæ or posterior nares. Later the upper portion of the mouth-cavity becomes part of the nasal cavity by the formation of the palatal processes of the maxillæ and palatine bones, so that finally the definitive hard palate is completed and the nasal cavities establish communication dorsally with the pharynx. The wide septum between the nasal pits narrows and becomes the nasal septum proper, dividing the nasal cavity into the paired nasal fossæ.

The lateral walls of the nasal fossæ, at first smooth and even, at an early time show grooves or furrows, the precursors of the nasal meatuses. The furrows delimit folds, the precursors of the nasal conchæ. Later cartilage develops within the epithelially covered mesenchymal conchæ which subsequently, together with that of the lateral nasal walls proper, undergoes ossification. The nasal mucous membrane also evaginates into neighboring bones, giving origin to the ethmoidal cells and the frontal, sphenoidal and maxillary sinuses, the initial points of outgrowth remaining as the ostia or apertures of the adult cells and sinuses.

The paranasal sinuses are preformed in the nasal meatuses and the secondary furrows that mold the lateral walls of the meatuses. This is true of all the paranasal sinuses save the sphenoidal which arises in connection with the posterior cupola of the cartilaginous nasal capsule, and in a sense is primarily a constriction of the nasal mucosa from the most dorsal and cephalic part of the nasal fossa. No paranasal sinus develops from the inferior nasal meatus. The pre-existing spaces from which paranasal sinuses and cells develop are: (1) the suprabullar recess; (2) the bullar furrow; (3) the infrabullar furrow; (4) the ethmoidal infundibulum, all of the descending ramus of the middle nasal meatus; (5) the frontal furrows; (6) the frontal recess, both of the ascending ramus of the middle nasal meatus; (7) the anterior extremity and the superior and inferior recesses of the superior nasal meatus; (8) the supreme nasal meatus; (9) the sphenoethmoidal recess.

THE LARYNX

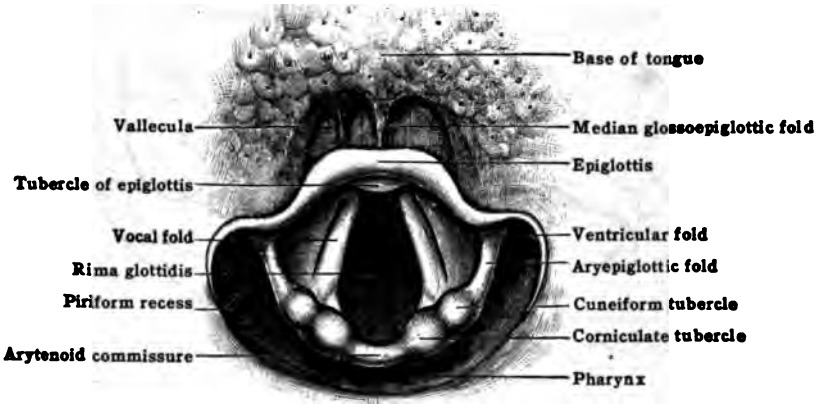
The **larynx** (figs. 968, 981, 982, 985), is a tubular organ, the framework of which consists of cartilages and elastic membranes. Its inner surface is covered by mucous membrane continuous with that of the pharynx above and the trachea below. From the membranes are formed a pair of **vocal folds** which, by the passage of air through the larynx, are thrown into vibration and so function in the generation of sound. These folds are affected in respect to their tension and in their mutual relation by the actions of a system of laryngeal muscles under the control of the vagus nerve and are made thereby, on the one hand, to produce those modifications of the sound involved in the voice and on the other hand to regulate the amount of air passing through the **cavity of the larynx.** The latter communicates above with the pharynx by means of an opening called the **laryngeal aperture,** and below with the cavity of the trachea. Figure 981 shows the laryngeal aperture with its boundaries, the epiglottis and the **aryepiglottic folds;** also the cavity of the larynx where, on the walls right and left, appear the **ven-**

tricular and the **vocal folds** with the chink called the **rima glottidis** separating **them**. The position of the larynx and some of its important parts can be well **seen** in a midsagittal section (fig. 983).

THE CARTILAGES OF THE LARYNX

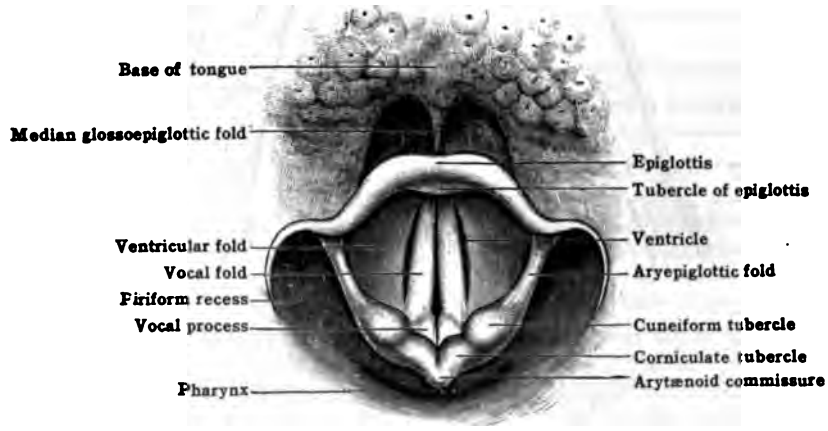
The **laryngeal cartilages** [cartilagines laryngis] are nine in number, three of **which** (cricoid, thyroid, epiglottic) are single and the rest in pairs (arytenoid, **corniculate**, cuneiform).

FIG. 981.—VIEW OF INTERIOR OF LARYNX AS SEEN FROM ABOVE DURING INSPIRATION.



The **cricoid cartilage** [cartilago cricoidea] (figs. 984, 986, 989), single, has been compared in its shape to a signet ring. Its position is at the lower end of the larynx, where it is connected with the first ring of the trachea. Posteriorly the cricoid cartilage expands into a broad **lamina**, approximately 25 mm. in height, which enters into the dorsal boundary of the laryngeal cavity, while laterally and ventrally it forms a narrow **arch** measuring but 8 mm. On either side of the upper margin of the lamina is the elliptical **arytenoid articular surface** [facies

FIG. 982.—VIEW OF INTERIOR OF LARYNX AS SEEN FROM ABOVE DURING VOCALIZATION.

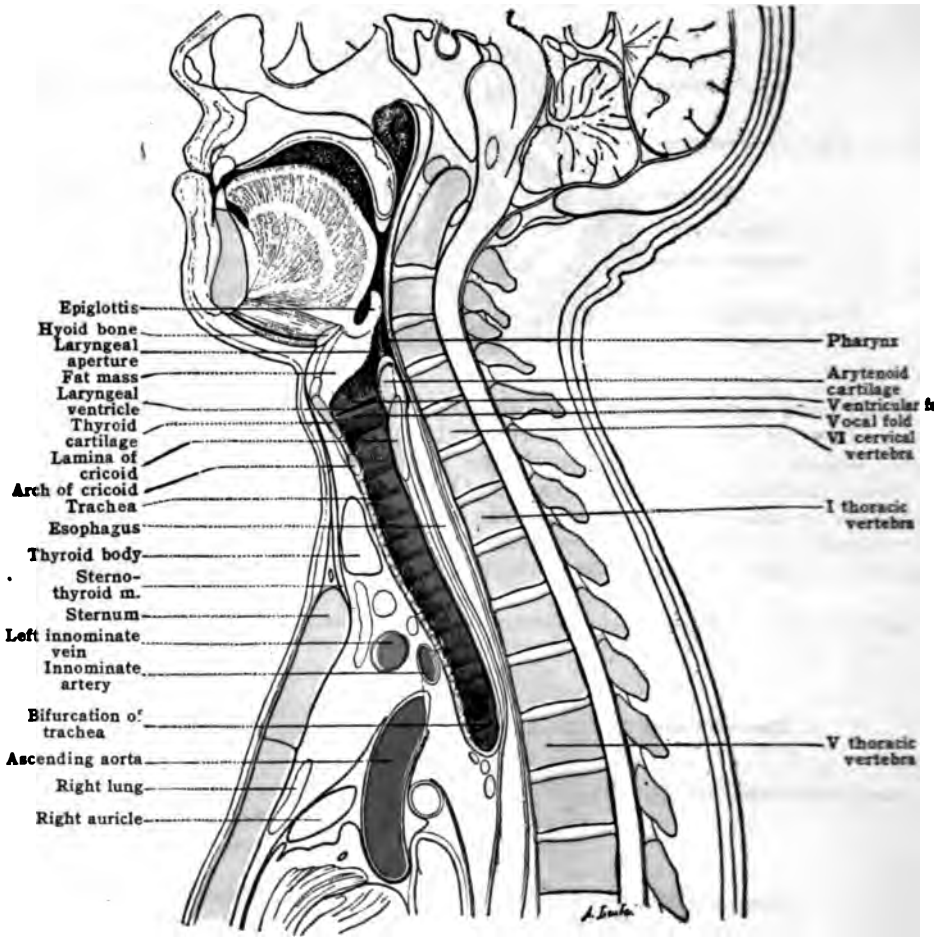


articularis arytænoidea], its long axis parallel with the margin of the cricoid, its steeply sloping surface convex for articulation with the arytenoid cartilage. The dorsal surface of the lamina presents a vertical median ridge which gives attachment to some of the longitudinal fibers of the esophagus and paired lateral impressions for the attachment of the posterior cricoarytenoid muscles. The arch, weakest in its middle part, presents concave upper and straight lower margins. A circular, elevated **thyroid articular surface** [facies articularis thy-

reoidea] for articulation with the inferior cornu of the thyroid cartilage is situated upon the side of the cricoid where arch and lamina are continuous. The internal surface is covered by the mucous membrane of the larynx.

The **thyroid cartilage** [cartilago thyreoidea] (figs. 984, 986, 988), single and the largest in the laryngeal skeleton, is composed of two broad **laminæ, right and left,** which meet and are fused ventrally in the midline, forming an angle of 90° with one another in the male and 120° in the female. The laminæ are stout, but their connection at the angle is through a weak strip of cartilage. The upper margin of each lamina is convex, and in front drops abruptly to form in the median line the **superior thyroid notch** [incisura thyreoidea superior]. The ventral edges

FIG. 983.—MEDIAN SECTION OF A MAN 21 YEARS OF AGE, SHOWING THE POSITION OF LARYNX AND TRACHEA. (After W. Braune, from Poirier and Charpy.)



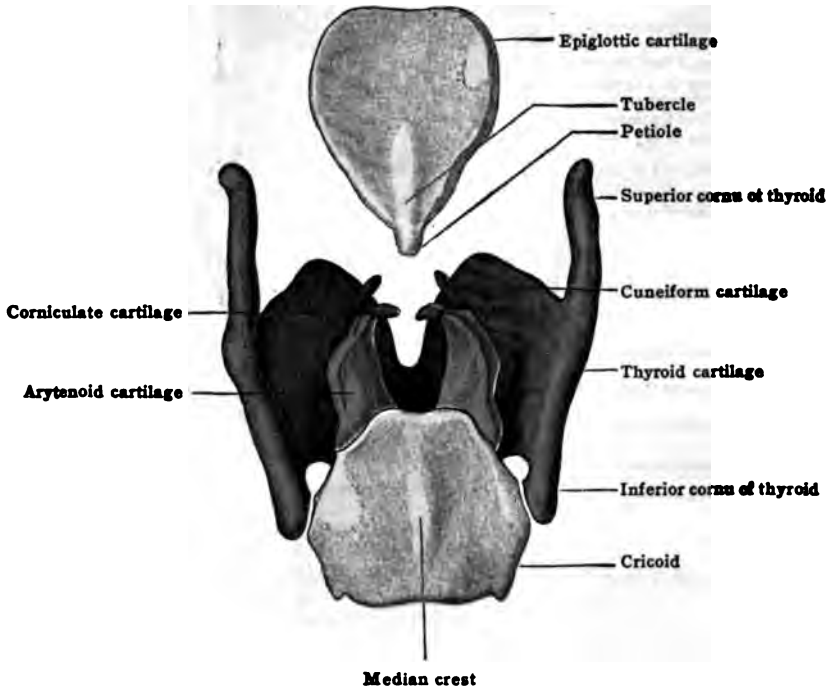
meeting in the angle produce the subcutaneous **laryngeal prominence** [prominentia laryngea] ('Adam's apple'), which is seen on the ventral aspect of the neck. The horizontal inferior margin presents near its middle the **inferior thyroid tubercle** [tuberculum thyreoideum inferius], and in the median line the **inferior thyroid notch** [incisura thyreoidea inferior]. The thick dorsal margin of each lamina is continued above the superior edge in the long **superior cornu** [cornu superius], and below the inferior margin in the short **inferior cornu** [cornu inferius]. The former is directed slightly dorsalward and medialward, and joins with the end of the greater cornu of the hyoid by a ligament. The inferior cornu, curving medialward as it descends, articulates by a flat, circular facet upon the medial side of its extremity with the thyroid articular surface of the cricoid cartilage. The external surface of the lamina affords attachment for muscles and presents in its

upper posterior part the **superior thyroid tubercle** [tuberculum thyreoideum superius]; in its lower part the **inferior thyroid tubercle.** The internal surface of the thyroid cartilage is smooth.

A thyroid foramen [foramen thyroideum], sometimes seen in the upper part of the lamina giving passage to the superior laryngeal artery, results from the incomplete union of the fourth and fifth branchial cartilages from which the laminæ are derived. The **oblique line** [linea obliqua], extending between the thyroid tubercles, is commonly present and is regarded by many anatomists as a normal feature of the external surface of the thyroid cartilage. It marks the attachment of the sternothyroid and thyrohyoid muscles. At the insertion of the vocal ligaments in the angle of the laminæ a small perichondral process is often observed.

The **arytenoid cartilages** [cartilagines arytænoideæ] (figs. 984, 988, 989, 990), paired, surmount the lamina of the cricoid cartilage and give attachment to the vocal ligaments, whose relations and state of tension are altered by the changes in position which these cartilages are almost constantly undergoing.

FIG. 984.—CARTILAGES OF THE LARYNX SEEN FROM BEHIND IN THEIR NATURAL POSITIONS. THE CUNEIFORM CARTILAGE IS SOMEWHAT HIGHER THAN NORMAL. (Merkel.)



Each cartilage is pyramidal in form, and molded for the attachment of several muscles. The **apex,** which is above, is bent dorsalward and medialward and is connected with a corniculate cartilage. The **base,** somewhat triangular in shape, presents at the lateral and dorsal part an oval or circular concave **articular surface,** directed medialward and caudalward to meet the arytenoid articular surface of the cricoid cartilage. The lateral angle of the base is prolonged into a stout **muscular process** for the insertion of the cricoarytenoid muscles, while the anterior angle is extended as a sharp projection, the **vocal process** [processus vocalis], which serves for the attachment of the vocal ligament. The surfaces of the arytenoid are medial, dorsal, and ventrolateral. The narrow **medial surface,** covered by the mucosa of the larynx, is nearly vertical, and faces the corresponding side of the opposite arytenoid, from which it is separated by a small space. The **dorsal surface** is concave for muscular attachment. The **ventrolateral surface** is the largest, and presents an irregular contour.

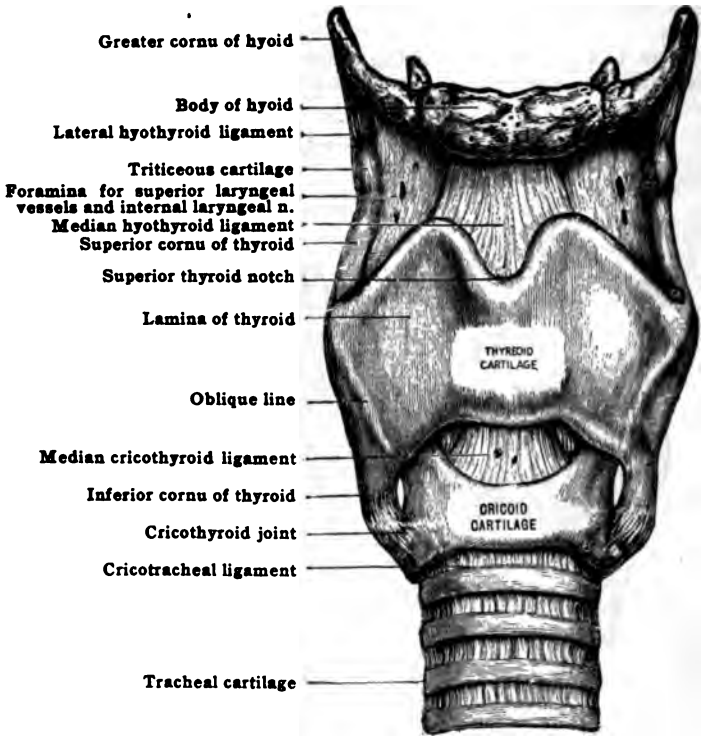
On this surface a ridge, the **arcuate crest** [crista arcuata], extends horizontally between two hollows—the **triangular fovea** [fovea triangularis] above, which lodges some mucous glands, and a larger depression below, the **oblong fovea** [fovea oblonga] for the vocal muscle. The **colliculus** is a small eminence found upon the ventral margin and ventrolateral surface.

The corniculate cartilages (of Santorini) [cartilagines corniculatæ (Santorini)] (figs. 984, 986, 988).—This pair of small conical cartilages is set upon the bent apices of the arytenoids, continuing their curves dorsalward and medialward.

The corniculate cartilage is not an independent structure in many lower animals, and its continuity with the arytenoid is sometimes met with in man where the two cartilages are normally developed in a continuous mass of tissue.

The **epiglottic cartilage** [cartilago epiglottica] (figs. 984, 988, 992, 998), unpaired, invested by mucosa behind and partly in front, thin and leaf-shaped, stands behind the root of the tongue and the body of the hyoid. It lies above the thyroid cartilage, in front of the entrance of the larynx. The free upper margin

FIG. 985.—FRONT VIEW OF THE LARYNGEAL SKELETON. (Modified from Bougery and Jacob.)



is convex, or notched; the lower end tapers to a short stalk, **the petiole** of the epiglottis [petiolus epiglottidis], to which the thyroepiglottic ligament is attached. The ventral surface is free above and covered by mucosa; in its lower part it is bound to the body of the hyoid, and is separated by a mass of fat from the hyothyroid ligament. Its dorsal surface above is saddle-shaped; below, it is convex, presenting the **epiglottic tubercle** [tuberculum epiglotticum]. To the margins are attached the aryepiglottic folds. The epiglottic cartilage presents numerous small holes and depressions for the accommodation of glands.

The **cuneiform cartilages (of Wrisberg)** [cartilagines cuneiformes (Wrisbergi)] (fig. 984) lie as small, rod-like bodies in the aryepiglottic folds anterior to the corniculate cartilages. They are variable in form and size and not rarely absent altogether.

These cartilages are parts of the epiglottic cartilage in some mammals where, as in man, they lie in the aryepiglottic folds. Their relations to the arytenoids are regarded as secondary. Sutton has shown that in the ant-eater a continuous rim of yellow elastic cartilage extends from the sides of the epiglottic cartilage to the summits of the arytenoids. A minute unpaired *interarytenoid* or *precricoid cartilage* is rarely present imbedded in the cricopharyngeal ligament and covered by the pharyngeal mucosa. It is a constant structure in certain mammals. A pair of small *sesamoid cartilages*, also constantly present in some mammals, is occasionally found in man at the lateral margins of the arytenoids, connected with them and with the corniculate cartilages by elastic ligaments.

Structure of the cartilages.—The thyroid, cricoid, and greater part of the arytenoid are composed of hyaline cartilage; the epiglottic, corniculate, and cuneiform cartilages, as well as the apex and vocal process of the arytenoid, are of elastic cartilage. Certain parts of the laryngeal skeleton normally undergo calcification and subsequent ossification. Calcification begins at about twenty years of age in the thyroid and cricoid cartilages, and later in the arytenoid. The process begins a little later in the female than in the male, and does not extend so rapidly. The extent to which the cartilages are ossified and the time occupied in the process vary considerably. The elastic elements are not involved in the process.

FIG. 986.—CRICOID AND ARYTENOID CARTILAGES, VENTRAL VIEW. (Rauber-Kopsch.)

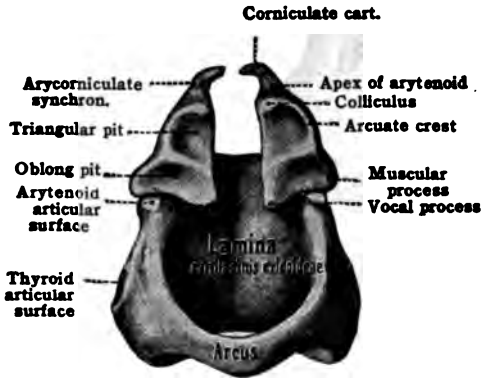


FIG. 987.—CRICOID AND ARYTENOID CARTILAGES SEEN FROM THE LEFT. (Rauber-Kopsch.)

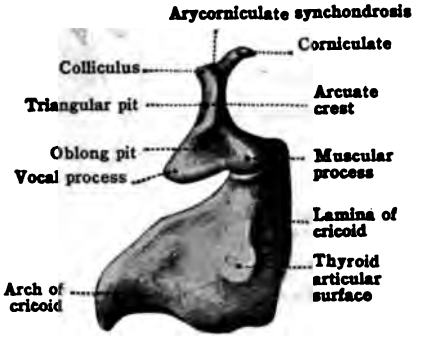

THE JOINTS AND MEMBRANES OF THE LARYNX

(A) THE ARTICULATIONS OF THE LARYNGEAL CARTILAGES

The cricothyroid articulation (figs. 984, 986).—The articular surfaces concerned are the thyroid articular surface on the lateral aspect of the cricoid and the articular surface on the inferior cornu of the thyroid cartilage. The **cricothyroid articular capsule** attached around the margins of these surfaces and certain accessory bands serve to bind the cartilages together. The capsule is lined by synovial membrane, forming a typical arthrodial joint.

The accessory bands, **ceratocricoid ligaments,** fall into three groups radiating from the inferior cornu: the **ligamenta ceratocricoidea posteriora** upward and medialward to the superior margin of the cricoid; the **ligamenta ceratocricoidea lateralia** downward at the side and back of the capsule; the **ligamentum ceratocricoideum anterius** downward and forward.

A rotary movement about a transverse axis of the cricoid upon the thyroid or *vice versa* and a slight backward and forward gliding are permitted at this joint.

The cricoarytenoid articulation (figs. 984, 988, 989).—The articular surface of the cricoid cartilage and the articular surface of the arytenoid which enter into this articulation are so disposed that at no time do they meet in complete apposition. A loose capsule [capsula articularis cricoarytænoidea] of fibrous and synovial strata attached around the edges of the joint surfaces unites the cartilages and encloses a cavity, forming a typical arthrodial joint.

The **posterior cricoarytenoid ligament,** attached above to the medial surface of the base and muscular process of the arytenoid, and below to the lamina of the cricoid, is important in helping to fix the former cartilage in place upon the sloping arytenoid articular surface of the cricoid and in limiting its movements. Motion at this articulation is very free. The following simple movements of the arytenoid are best understood: (1) gliding of the arytenoid toward or away from its fellow; (2) inclining ventrally and dorsally; (3) rotating on a vertical axis, so that the vocal process sweeps medialward or lateralward and also a little caudalward or cephalad.

The arycorniculate articulation [synchondrosis arycorniculata] is the union of the apex of the arytenoid cartilage with the corniculate cartilage. It is usually formed by connective tissue; rarely is there a joint cavity.

The thyroepiglottic union is accomplished by the strong, elastic **thyroepiglottic ligament** (fig. 988) connecting the petiole of the epiglottic cartilage with the thyroid cartilage, caudal and dorsal to the superior notch.

(B) The Elastic Membrane of the Larynx

The elastic membrane of the larynx [membrana elastica laryngis] **is a name** given to a more or less continuous sheet of elastic fibers connected **with the**

Fig. 988.—The Laryngeal Skeleton, Dorsal View. (Modified from Poirier and Charpy.)

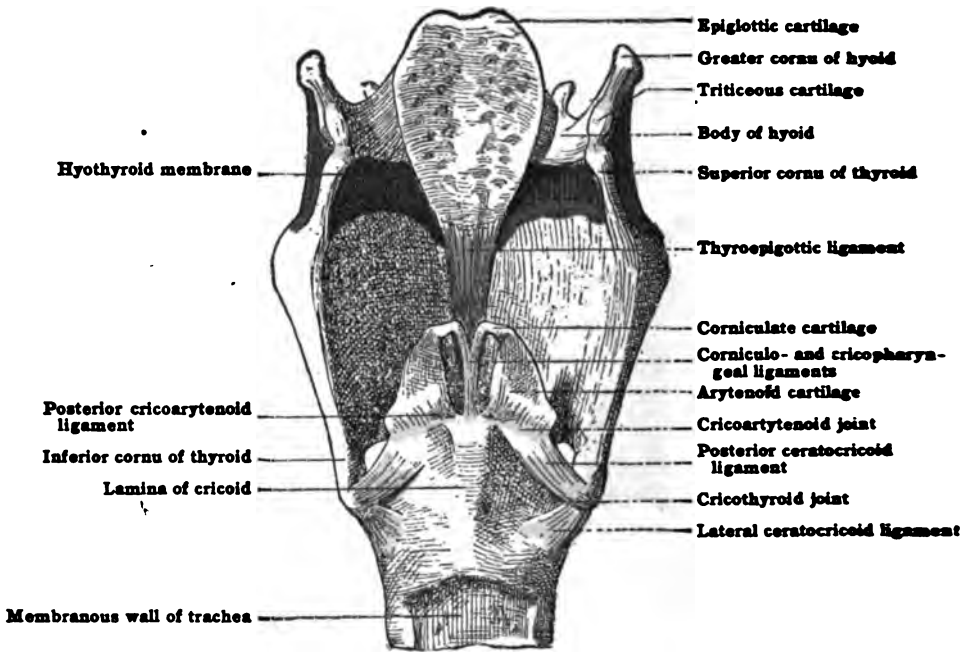

Fig. 989.—The Larynx with its Ligaments, Viewed from the Right. (The right lamina of the thyroid cartilage has been removed.) (Spalteholz.)

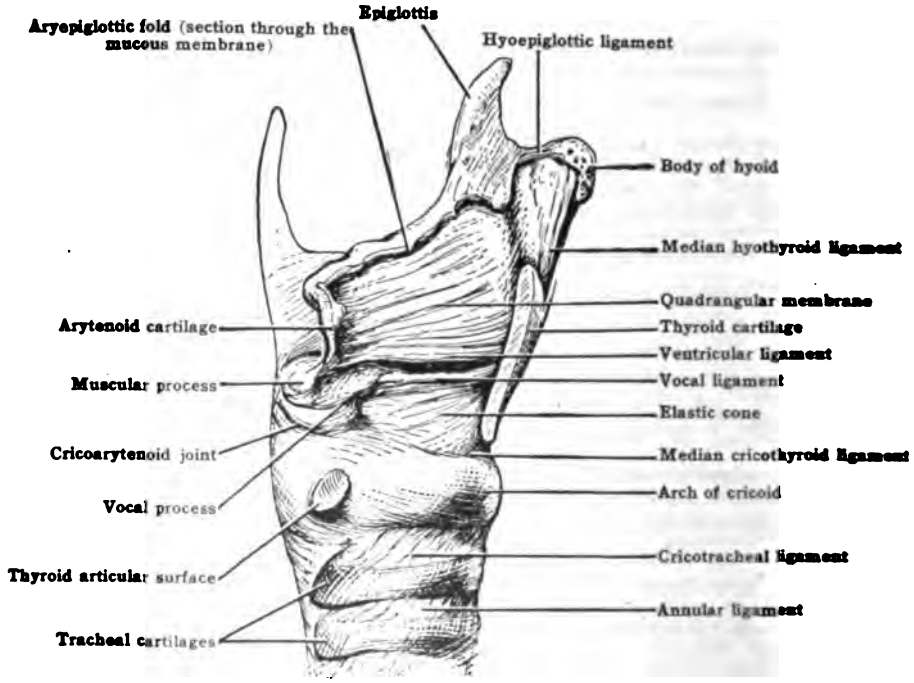
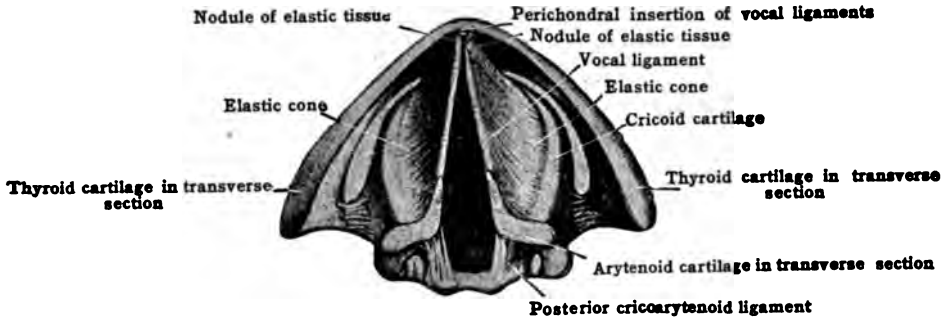


deeper parts of the laryngeal mucosa. Its upper part is known as the *quadrangular membrane,* the lower part as the *elastic cone.* A middle region of the elastic membrane lies opposite the ventricle of the larynx.

The quadrangular membrane (figs. 989, 992) extends from the aryepiglottic folds above to the level of the ventricular folds (false vocal cords) below. The lateral parts of this membrane are widely separated cephalically, but they converge toward the middle line as they descend. Ventrally, the membrane is fixed in the angle of the thyroid laminæ and to the sides of the epiglottic cartilage; dorsally, to the corniculate cartilages and to the arytenoids. The cephalic edge on either side lies within the aryepiglottic fold, which it supports; it slopes caudalward and dorsalward and includes the cuneiform cartilage. The caudal edge, horizontal and in a sagittal plane, is best developed ventrally, where it is attached in the angle of the thyroid a little way from the middle line; dorsally, it is fixed to the medial margin of the triangular fovea of the arytenoid. This caudal free margin, differentiated as the **ventricular ligament** [lig. ventriculare], is enclosed within, and is the support for the ventricular fold.

FIG. 990.—THE ELASTIC CONE SEEN FROM ABOVE. (Modified from Luschka.)



The elastic cone [conus elasticus] (figs. 989, 990) extends from the level of the vocal folds to the cephalic margin of the cricoid cartilage. Its component fibers are attached in the re-entrant angle and adjacent caudal margin of the thyroid cartilage, whence they spread caudalward and dorsalward to the cephalic edge of the cricoid arch and to the arytenoid cartilages. The strong ventral portion, perforated by vessels, is the **median cricothyroid ligament** (figs. 985, 986). The lateral parts (lateral portions of the cricothyroid membrane) present cephalic free edges, somewhat thickened, which, running horizontally near the middle line from the thyroid angle to the vocal processes, constitute the **vocal ligaments.** These are inserted ventrally into a perichondral process in the thyroid angle; dorsally, they have a wide area of attachment to the cephalic and medial surfaces of the vocal processes of the arytenoids with the elastic fibers of which they are in part continuous. A yellowish, cellular nodule (sometimes cartilage) occurs in the ventral end of each ligament. The vocal ligaments enter into the formation of the vocal folds (true vocal cords).

(C) CONNECTIONS BETWEEN THE LARYNX AND NEIGHBORING STRUCTURES

The **hyothyroid membrane** [membrana hyothyreoidea] (figs. 988, 991, 992) is a loose, fibrous, elastic sheet, binding together the thyroid cartilage and hyoid bone. It extends from the cephalic margin of the former to the greater cornua and cephalic margin of the body of the latter. The superior laryngeal artery and vein and the internal laryngeal nerve pass through it from the side. Its dorsal and lateral edge is cord-like, consisting of elastic fibers which stretch as the **lateral hyothyroid ligament** from the superior cornu of the thyroid to the greater cornu of the hyoid. A small **cartilago triticea** is sometimes present in this band. The middle part, **median hyothyroid ligament,** thick and elastic, extends from the superior thyroid notch upward behind the body of the hyoid to be attached to its cephalic margin, the *hyoid bursa* being interposed between the bone and the membrane.

The cartilago triticea is the remains of a connection between the thyroid and hyoid present in the embryo. It persists in adult life in some lower animals.

The **hyoepiglottic ligament** [lig. hyoepiglotticum] (figs. 989, 992) connect ventral surface of the epiglottic cartilage with the cephalic margin of the body the greater cornua of the hyoid. It is a broad sheet, lying above a mass

FIG. 991.—THE LARYNX SEEN FROM THE LEFT SIDE. (Modified from Luschka

which stands between the median hyothyroid membrane and the epig and spreading laterally to join the pharyngeal aponeurosis in the region piriform recess.

The name *glossoepiglottic ligament* is given to the elastic fibers extending between the root of the tongue and the epiglottis within the median glossoepiglottic fold.

The **corniculopharyngeal ligament** (fig. 988) extends from the corniculate cartilage caudalward and toward the median line, attaching to the mucosa of the pharynx and joining its

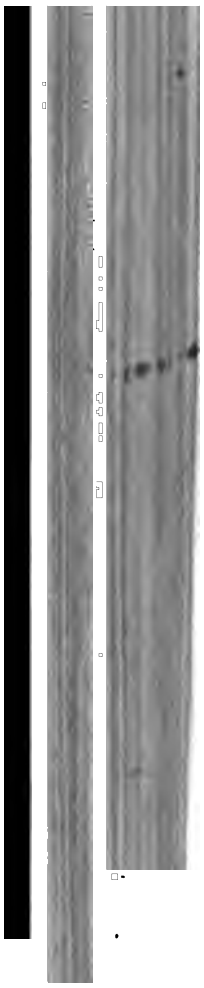
fellow behind the arytenoid muscle. From this point a single band, the **cricopharyngeal ligament**, which may enclose a nodule of cartilage (**the interarytenoid cartilage**), descends in the middle line, to be fixed to the cricoid lamina and into the pharyngeal mucosa.

The larynx and trachea are united by fibrous membrane, the **cricotracheal ligament** [lig. cricotracheale] (figs. 985, 989), between the inferior margin of the cricoid cartilage and the cephalic margin of the first tracheal ring. Dorsally the ligament is continued into the membranous wall of the trachea.



fibers and are supplied by the vagus nerve through its laryngeal br
principal intrinsic laryngeal muscles are (1) the *cricothyroid*, (2

of the pharynx together with their common nerve-supply indicate their

The **posterior cricoarytenoid** muscle [m. cricoarytaenoideus p
991, 993), paired, is situated at the back of the larynx, covered
cous coat of the pharynx. It is a thick, triangular mass which fa
the posterior surface of the cricoid lamina, the two muscles being
by the median crest of the cartilage. The lower fibers ascend and
pass horizontally lateralward and are inserted into the muscular
arytenoid cartilage on its dorsal surface at its

W

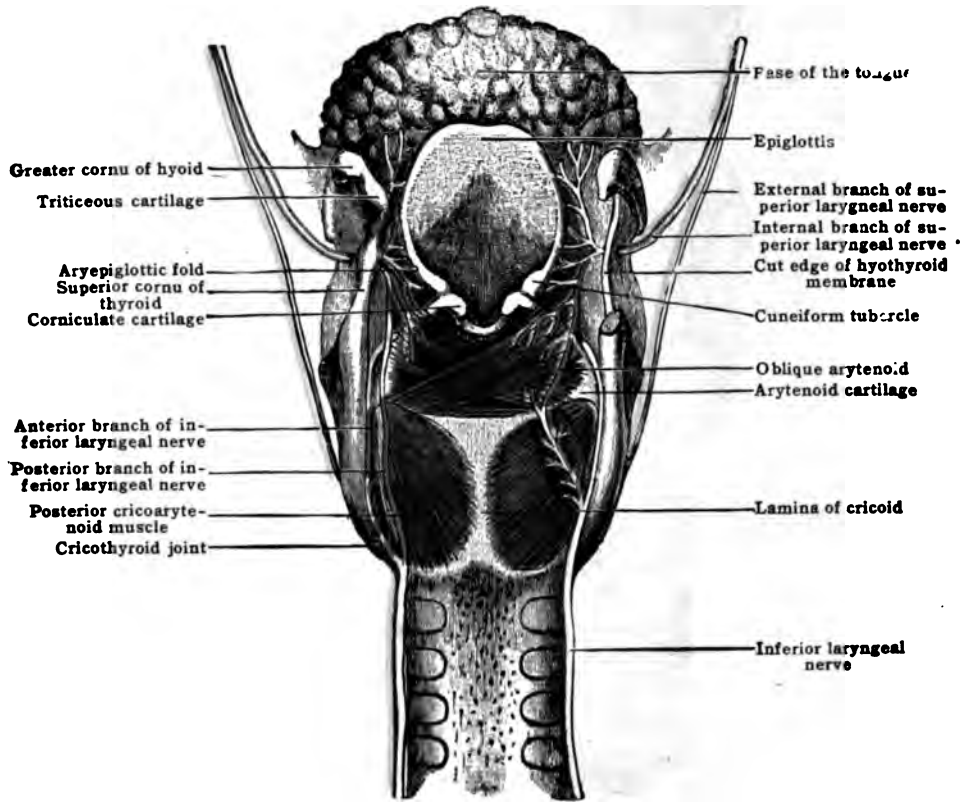
transverse arytenoid

The **lateral cricoarytenoid** muscle [m. cricoarytænoideus lateralis] (fig. 992) arises from the upper margin and outer surface of the cricoid arch and from the elastic cone, whence the fibers extend backward and upward to an insertion on the anterior surface of the muscular process of the arytenoid cartilage. This muscle is inseparable from the thyroarytenoid in about half the cases.

The lateral cricoarytenoids by their contraction cause the vocal processes to move toward the median line and a little downward, so that the vocal ligaments are approximated and slightly stretched. They antagonize the posterior cricoarytenoids. The anterior branch of the inferior laryngeal nerve supplies these muscles.

The **external thyroarytenoid** muscle [m. thyreoarytænoideus (externus)] (figs. 992, 995, 999), variable in form and in the disposition of its fibers, is closely connected with the preceding. It lies under cover of the thyroid lamina lateral

FIG. 996.—THE MUSCLES AND NERVES OF THE LARYNX. DORSAL VIEW.



to the laryngeal saccule (ventricular appendix) and elastic cone. Arising within the angle of the thyroid laminæ, the muscle extends upward and backward to its insertion on the lateral margin of the arytenoid cartilage.

It draws forward the arytenoid cartilage (and also tilts the cricoid), and rotates it so that the vocal process passes forward, medialward and downward, relaxing the vocal ligament. It is the antagonist of the cricothyroid (fig. 995). Its nerve-supply is the anterior branch of the inferior laryngeal.

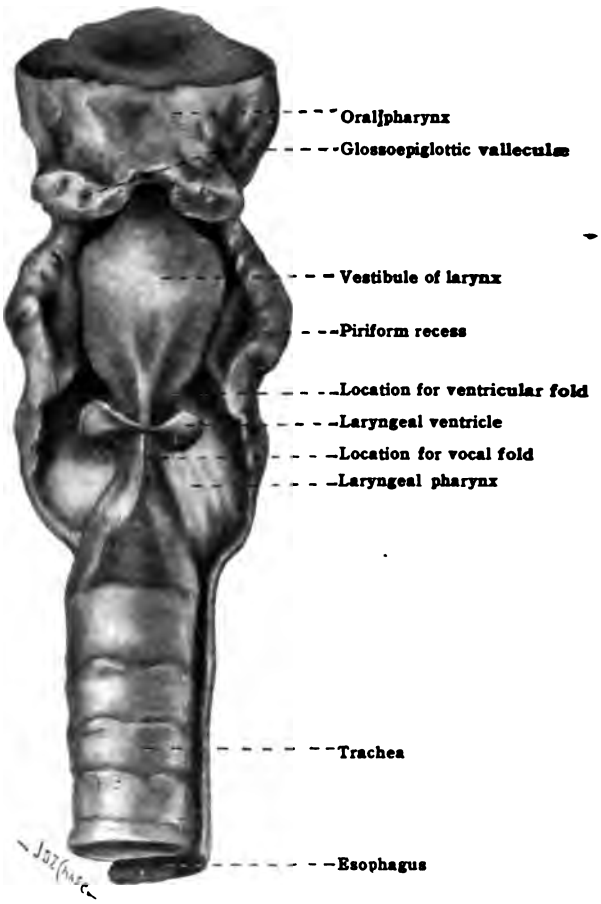
The **vocal muscle** [m. vocalis], (fig. 999), prismatic in form, is the inner constant part of the thyroarytenoid. It lies in the vocal lip lateral to the vocal ligament. Its fibers run from their origin in the angle of the thyroid laminæ to their insertion in the vocal process and oblong fovea of the arytenoid cartilage.

It draws forward the vocal process, relaxing the vocal ligament. Its nerve comes from the anterior branch of the inferior laryngeal. The insertion of certain fibers of this muscle into the elastic vocal ligament has been observed (aryvocalis muscle of Ludwig). D. Lewis has shown that some of the elastic fibers in the vocal ligament are derived from the perimysium of the vocal muscle.

The **ventricular muscle** [m. ventricularis] consists of a few fibers derived from the th arytenoid which reach the back of the laryngeal saccule and enter the ventricular fold. small *thyroarytenoideus superior* extends from the angle of the thyroid to the muscular pr of the arytenoid upon the lateral surface of the main muscle.

The **thyroepiglottic** muscle [m. thyrœpiglotticus] is a fairly constant p muscle closely connected with the thyroarytenoid (fig. 992). It originates the inner surface of the thyroid lamina and proceeds upward and backwa end in the quadrangular membrane and in an insertion on the lateral bor the epiglottis.

FIG. 997.—CAST OF LARYNX, PHARYNX, ETC. VENTRAL ASPECT. From a cast by J. I the Daniel Baugh Institute of Anatomy of the Jefferson Medical College.



SUMMARY OF THE ACTIONS OF THE LARYNGEAL MUSCLES

According to their actions, the laryngeal muscles may be divided into—(*a*) those w effect the tension of the vocal folds; (*b*) those which control the rima glottidis; (*c*) those w effect the closure of the laryngeal aperture and vestibule.

(*a* The vocal ligaments are made tense by the action of the cricothyroid, the lateral posterior cricoarytenoid and the transverse arytenoid muscles. The vocal ligaments ar laxed at the result of the action of the external thyroarytenoid and vocal muscles.

(*b*) The rima glottidis is widened by the posterior cricoarytenoid and made narrow by contraction of the transverse and oblique arytenoids. The lateral cricoarytenoideus assists in closing the rima glottidis by rotating the vocal processes medialward, and if the terior cricoarytenoid contracts simultaneously, it aids in the closure. The vocal ligament approximated also by the thyroarytenoideus (externus).

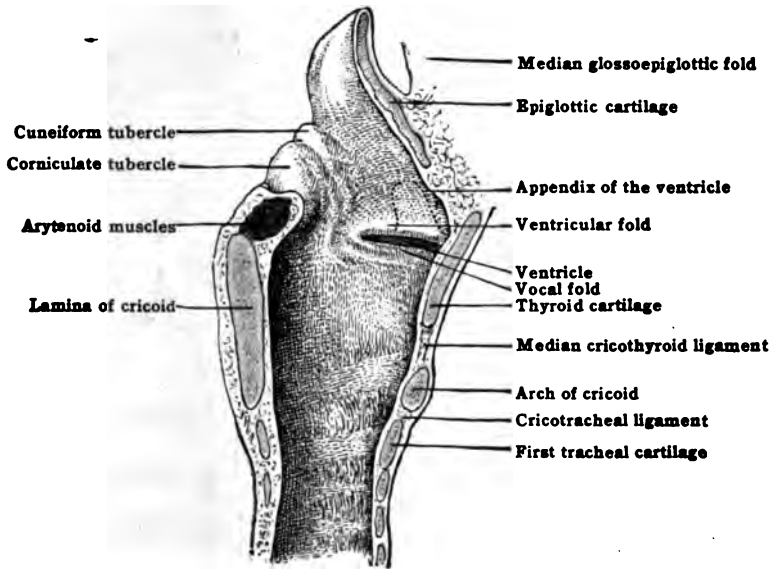
(*c*) The superior laryngeal aperture (aditus) and vestibule are closed mainly by the t verse arytenoid and thyroarytenoid (externus), by which the arytenoid cartilages are bro into apposition and drawn toward the epiglottis. Together these muscles form a sphinct the laryngeal vestibule. Other muscles derived from the constrictor group, the oblique a noid and aryepiglottic, assist in closing the laryngeal aperture.

CAVITY OF THE LARYNX AND LARYNGEAL MUCOSA

The **cavity of the larynx** [cavum laryngis] is relatively narrow and does not correspond in shape with the outer surface of the organ. Its form is shown in figs. 979 and 997 taken from casts of the laryngeal cavity and the spaces continuous with it. Its walls are covered throughout by the **mucous membrane** of the larynx (figs. 998, 999). The mucosa of the larynx is continuous above with the mucous membrane of the pharynx, below with that of the trachea (figs. 981, 982). At the root of the tongue the pharyngeal mucosa is reflected backward to the anterior surface of the epiglottis, presenting the **median** and **lateral glossoepiglottic folds** [plica glossoepiglottica mediana; lateralis]. From the sides of the pharynx it passes medialward, first sinking between the thyroid cartilage laterally and the arytenoid and cricoid medially, lining the walls of the *piriform recess;* then passing over the margin of the aryepiglottic fold to enter the vestibule of the larynx.

At the medial side of the piriform recess a slight fold of the mucosa [plica nervi laryngei] corresponds to the superior laryngeal nerve. Between the root of the tongue and the epiglottis is a depression on either side of the middle line and limited by the median and lateral

FIG. 998.—MEDIAN SECTION OF THE LARYNX. (Merkel).



glossoepiglottic folds; this is the **epiglottic vallecula** [vallecula epiglottica]. The piriform recess and the epiglottic vallecula are favorite sites for the lodgment of foreign bodies. The **aryepiglottic fold** [plica aryepiglottica] extends from the side of the epiglottis to the apex of the arytenoid cartilage; within it are fibers of the aryepiglottic and thyroepiglottic muscles and the cuneiform and corniculate cartilages. These cartilages correspond to two rounded eminences on each side of the laryngeal entrance, the **cuneiform** and **corniculate tubercles** [tuberculum cuneiforme (Wrisbergi); tuberculum corniculatum (Santorini)], respectively. Of these, the former is often small and inconspicuous, the latter usually well developed and prominent (fig. 998).

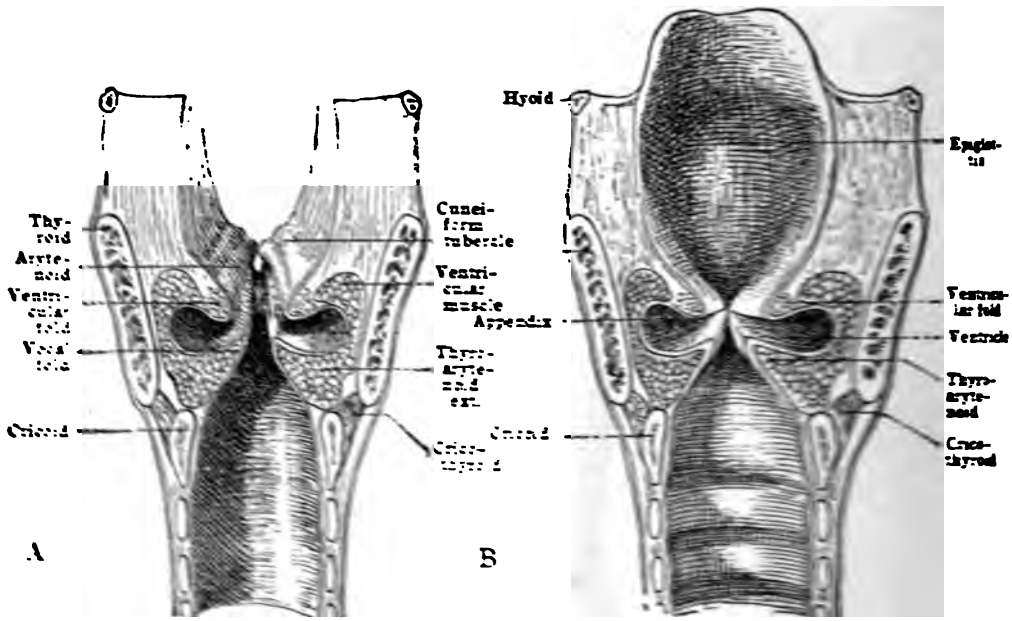
The cavity of the larynx above the level of the ventricular folds (false vocal cords) is known as the **vestibule** [vestibulum laryngis]. This is wide in its cephalic part, but the sides incline toward the median line in descending, and the cavity becomes narrow transversely in approaching the region of the glottis. Here the cavity is termed the **superior entrance to the glottis** [aditus glottidis superior]. The parts of the framework of the larynx which enter into the walls of the vestibule are: ventrally, the epiglottic and thyroid cartilages with the thyroepiglottic ligament; laterally, the quadrangular membrane, the cuneiform and corniculate cartilages, and the medial surface of the arytenoid cartilage; dorsally, the anterior surface of the transverse arytenoid muscle. The vestibule communicates with the pharynx by the **laryngeal aperture** [aditus laryngis] (figs. 981, 982, 983, 998), which looks cephalically and dorsally. The form of the aperture is oval or triangular, with the base directed ventrally; here it is bounded

by the epiglottis; laterally by the aryepiglottic fold, of the mucosa. Dorsally the laryngeal aperture is prolonged as a little notch between the corniculate cartilages and the apices of the arytenoids [**incisura interarytænoidea**], limited behind by a commissure of the mucosa.

The high ventral wall of the vestibule presents a marked convexity, the **tubercle of the epiglottis** [tuberculum epiglotticum], over the thyroepiglottic ligament. The lateral walls, higher ventrally than dorsally, show two slight ridges, separated by a shallow groove, extending caudalward from the cuneiform and corniculate tubercles. The dorsal wall, very low, corresponds to the commissure connecting the arytenoid cartilages.

The **ventricular folds** [plicæ ventriculares] or 'false vocal cords' are prominent rounded folds of mucous membrane extending ventrodorsally, one on each side of the rima vestibuli (figs. 981, 982, 998, 999). The folds are most prominent in their ventral half, reaching the angle between the laminæ of the thyroid cartilage. They gradually fade away dorsally, but fall short of the dorsal laryngeal wall.

FIG. 999.—FRONTAL SECTION OF A LARYNX HARDENED IN ALCOHOL. A Posterior segment. B. Anterior segment. Poirier and Charpy.



correspond in the ventrodorsal extent to the vocal ligaments, and stand nearer the median line than the ventricular folds. In color the vocal folds are pearly white, excepting the ventral end of each, where there is a **yellow spot** [macula flava] produced by a little mass of elastic tissue (sometimes cartilage) in the ligament. The **vocal lip** [labium vocale] on each side forms the floor of the related laryngeal ventricle and contains the upper part of the elastic cone, whose thickened free edge, the vocal ligament, lies in the vocal fold and along the vocal muscle. The two vocal lips with the vocal folds and the intervening space, the rima glottidis, together constitute the sound-producing apparatus, the **glottis.**

The **rima glottidis** (figs. 981, 982, 999) the narrowest part of the laryngeal cavity, is an elongated slit between the vocal folds and the medial surfaces of the arytenoid cartilages, extending from the transverse arytenoid muscle dorsally to the thyroid cartilage ventrally. The portion of the rima between the vocal folds is known as the **pars intermembranacea,** that between the arytenoids the **pars intercartilaginea.** The rima glottidis in easy respiration is narrow and has the form of a long triangle; in labored breathing it is widely open and lozenge-shaped.

Below the level of the vocal folds is the space called the **inferior entrance to the glottis** [aditus glottidis inferior] (fig. 999), which is narrow from side to side above, wide and circular in section below—altogether somewhat funnel-shaped. Its walls are formed by the elastic cone and by the arch and lamina of the cricoid cartilage. The lining mucosa is separated from the elastic cone by numerous glands and loosé connective tissue, a condition favorable to the development of edema; below it is continuous with the mucosa of the trachea.

By means of the **laryngoscope** a more or less complete picture of the laryngeal aperture and the cavity of the larynx can be obtained (figs. 981, 982). Cranialward there appear the root of the tongue with the epiglottic valleculæ and glossoepiglottic folds leading dorsalward to the epiglottis; dorsal to the latter, the triangular aperture of the larynx, bounded laterally by the aryepiglottic folds. Farther lateralward appear the piriform recesses, as transverse fissures behind the laryngeal aperture. Within the aryepiglottic folds are seen the prominent corniculate tubercles on either side of the interarytenoid commissure and just ventral, the variable cuneiform tubercles. Within the vestibule the epiglottic tubercle rises upon the ventral wall, while laterally appear the ventricular folds overhanging the slit-like openings of the laryngeal ventricles. Below this level the vocal folds stand out on either side approaching nearer the median plane than do the ventricular folds and conspicuous by their pearly whiteness. The form and extent of the rima glottidis and of its divisions, the intermembranous and intercartilaginous parts, can be inspected. Far down, the cricoid cartilage and ventral wall of the trachea may appear and under favorable conditions a glimpse of the bifurcation of the latter can be obtained.

The **mucous coat of the larynx** [tunica mucosa laryngis] in general is covered by a ciliated epithelium; the vocal lips, and, exceptionally, small areas of the mucosa of the laryngeal surface of the epiglottis and the ventricular folds possess a covering of flat, non-ciliated cells. The attachment of the mucosa to the underlying parts is very firm about the vocal folds and dorsal side of the epiglottis, but loose in the aryepiglottic folds, where much areolar tissues is present. In general the mucosa is pink in color becoming bright red over the epiglottic tubercle and edges of the epiglottis and fading over the vocal folds, which appear almost white.

Numerous **mucous glands** [glandulæ laryngeæ] occur about the larynx and are aggregated into groups in certain places. One cluster of **anterior glands** is found in front of and on the posterior side of the epiglottis; another, the **middle glands,** is in the ventricular fold, in the triangular fovea of the arytenoid cartilage and clustered about the cuneiform cartilage, while a third set, the **posterior glands,** is disposed about the transverse arytenoid muscle. Many glands pour their secretion into the appendix of the laryngeal ventricle, but there are none on or about the vocal folds. **Lymph-nodules** of the larynx occur in the mucosa of the ventricle and on the posterior surface of the epiglottis.

Position and relations.—The larynx opens above into the pharynx by the aditus and in this region is connected with the hyoid bone. Below, its cavity leads into the trachea. Its position in the neck is indicated on the surface by the laryngeal prominence (Adam's apple). It stands ventral to the fourth, fifth, and sixth cervical vertebræ; from these it is separated by the prevertebral muscles and fascia and the laryngeal portion of the pharynx. The integument and cervical fascia cover the larynx ventrally in the middle line, while toward the side are the sternohyoid, sternothryoid, and thyrohyoid muscles. The lateral lobe of the thyroid gland and the inferior constrictor of the pharynx are in relation to it laterally, while further removed are the great vessels and nerves of the neck.

Peculiarities of age and sex. Position.—The larynx is placed high in the neck in fetal and infantile life and descends in later life. In a six-months fetus the organ is two vertebræ higher than in the adult. (Symington.) The descent of the larynx has been attributed to the vertical growth of the facial part of the skull, but this cause is questioned by Cunningham, who points out the high position of the larynx in the anthropoid apes, where the facial growth is more striking than in man; it appears also that the larynx follows the thoracic viscera in their subsidence, which, according to Mehnert, continues until old age. At birth the interval be-

tween the hyoid bone and thyroid cartilage is relatively very small and increases but little during early life.

Growth and form (cf. p. 47).—The larynx of the newborn is relatively large and in contour more rounded than that of the adult. The organ continues to grow until the third year, when a resting period begins, lasting until about twelve years of age, during which time there appears to be no difference between the larynx of the male and that of the female. At puberty, while no marked change is observable in the larynx of the female, rapid growth accompanied by modification of form of the larynx is initiated in the male. The laryngeal cavity is enlarged, the ventrodorsal diameter markedly increased; the whole framework becomes stronger; the thyroid cartilage especially increases greatly in its dimensions, giving rise to the laryngeal prominence; the vocal folds are lengthened and thickened, the voice changing in quality and pitch. These changes are, for the most part, effected in about two years, but complete development is not attained before twenty to twenty-five years of age. Castration is known to influence the development of the larynx, for in the eunuch it has been found to resemble that of a young woman. The changes in the structure of the cartilages have already been described.

Dimensions.—In the male the distance from the upper edge of the epiglottis to the lower margin of the cricoid is 70 mm.; in the female, 48 mm. The transverse diameter is 40 mm. in the male, 35 mm. in the female. The greatest sagittal diameter is 40 mm. in the male, 37 mm. in the female. The *vocal folds* in the male measure relaxed about 15 mm., in the female but 11 mm.; when stretched, about 20 mm. and 15 mm. respectively.

The length of the *rima glottidis* in the quiescent state is on the average 23 mm. in the male, 17 mm. in the female. In the male the *pars intermembranacea* measures 15.5 mm., the *pars intercartilaginea*, 7.5 mm. In the female these are 11.5 mm. and 5.5. mm. respectively. The rima may be lengthened by stretching of the vocal folds to 27.5 mm. in the male and 20 mm. in the female. (Moura.) In the male the width of the rima glottidis is 6–8 mm. in its widest part, but may be increased nearly to 12 mm.

Vessels and nerves (figs. 991, 996).—The *arteries* supplying the larynx are the superior and inferior laryngeal, which accompany the internal and inferior largyneal nerves respectively, and the cricothyroid arteries (see pp. 580, 604). The superior and inferior laryngeal veins join the superior and inferior thyroid veins respectively. The *lymph* vascular system is well developed throughout the larynx generally, but in the vocal folds where the mucosa is thin and tightly bound down the vessels are scarce and small in size (see p. 751).

The *nerves* of the larynx are the superior and inferior laryngeal branches of the vagus and also certain branches of the sympathetic. Taste-buds occur and are abundant in the mucosa of the posterior surface of the epiglottis. The innervation of the muscles has already been indicated, and the description of the course and relations of these nerves will be found in the chapter on the PERIPHERAL NERVOUS SYSTEM. It should be mentioned here, however, that the idea of sharply limited territories of innervation, not only for the mucosa, but for the muscles as well, has been brought into question by the researches of Semon and Horsley, Exner, and others, which show that the distribution and functions of the laryngeal nerves are extremely complex.

The development of the larynx.—The larynx is developed partly from the lower portion of the embryonic pharynx and partly from the upper portion of the trachea (see p. 471). The cricoid cartilage represents the uppermost tracheal cartilage, while the thyroid is formed by the fusion of four cartilages representing the ventral portions of the cartilages of the fourth and fifth branchial arches. The laryngeal muscles are derived from the musculature of these arches and consequently their nerve-supply is from the vagus. Whether or not the arytenoid and epiglottic cartilages are also derivatives of the branchial arches is uncertain, although it seems probable that they are.

THE TRACHEA AND BRONCHI

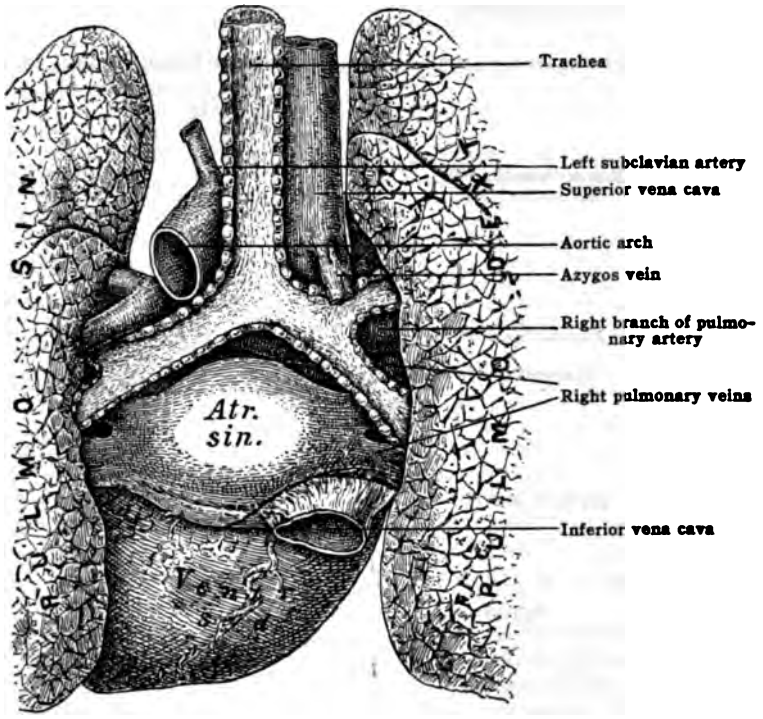
The tubular **trachea** (figs. 968, 983, 1000), or windpipe, extends from the larynx downward through the neck and into the thorax to end by dividing into two branches, the **right** and **left bronchi** [bronchus (dexter et sinister)], which lead to the lungs. These tubes are simple transmitters of the respiratory air. Their walls are, for the most part, stiff and elastic, consisting in large part of cartilage. While the general form of these tubes is cylindrical, a rounded contour is presented by their walls only in front and at the sides, the posterior surface being flat. The inner surface of the walls of the tubes presents a succession of slight annular projections caused by the cartilaginous rings which enter into their structure (fig. 997). The caliber of the trachea varies at different levels, a cast of the lumen being in general spindle-shaped. Its sectional area is less than the combined sectional areas of the two bronchi. When the **bifurcation of the trachea** [bifurcatio trachеæ] is viewed by looking down into its cavity, a sagitally directed keel, the *carina trachеæ* (fig. 1001), is seen between the openings which lead into the bronchi.

Position and relations (figs. 983, 1000, 1004).—The trachea lies in the median plane, extending from the level of the sixth cervical vertebra caudalward and dorsalward, receding from the surface in following the curve of the vertebral column, and deviating a little to the right, reaches the level of the fourth or fifth thoracic vertebra, where it divides. Its caudal end is fixed so that with elevation and descent of the larynx the tube is stretched and contracted, changes in length

which also result from extension and flexion of the head and neck. The mobility of the trachea is favored by its loose investment of connective tissue.

About half of the trachea lies in the neck, but the extent varies with the length of the neck, the position of the head and with age; the trachea holds a lower position in adult life than in childhood and a still lower one in old age when the bifurcation may be as low as the sixth or seventh thoracic vertebra. Ventrally and closely connected with the trachea is the isthmus of the thyroid gland, covering usually the second to fourth cartilages; ventral to this the cervical

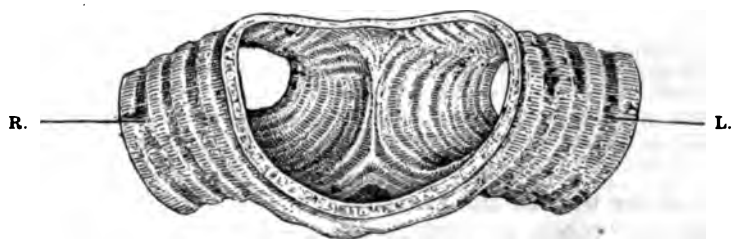
FIG. 1000.—TRACHEA AND BRONCHI IN THEIR RELATIONS TO THE GREAT VESSELS AS SEEN FROM BEHIND. (After Gegenbaur.)



fascia and integument. More caudally, the trachea is related ventrally to the inferior thyroid veins and some tracheal lymph-glands, and sometimes a thyroidea ima artery. The innominate artery occasionally crosses the trachea obliquely in the root of the neck. Dorsal to the trachea, in its whole length, lies the esophagus, which in this part of its course inclines to the left. On either side are the great vessels and nerves of the neck, and the lobes of the thyroid gland. The inferior laryngeal nerve lies in the angle between the esophagus and trachea.

Within the thorax the trachea lies in the mediastinum, enveloped in loose areolar tissue and fixed through strong fibrous connections with the central tendon of the diaphragm. The

FIG. 1001.—BIFURCATION OF THE TRACHEA SHOWING THE TRACHEAL KEEL. R. L., Right and left bronchi. (Heller and von Schroetter, from Poirier and Charpy.)

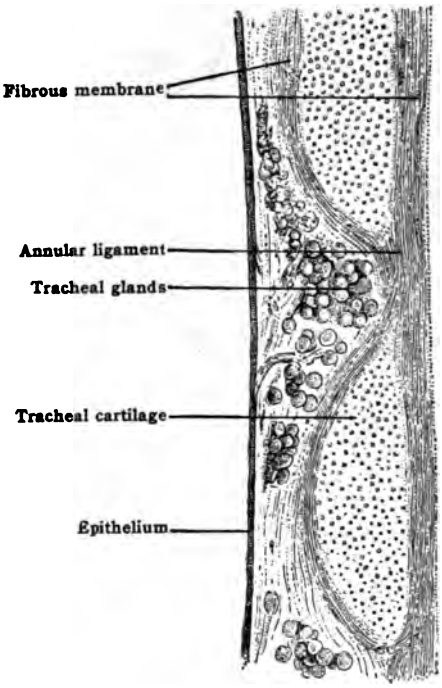


innominate artery and the left common carotid are at first ventral and then lateral as they ascend, while the left innominate vein and the remains of the thymus are further ventralward. The aortic arch is in contact with the ventral surface of the trachea near the bifurcation. On the right side are the vagus nerve, the arch of the vena azygos, the superior vena cava, and the mediastinal pleura; on the left, the arch of the aorta, the left subclavian artery, and the inferoir laryngeal nerve. A large group of **bronchial lymph-glands** [lymphoglandulæ bronchiales] lies caudal to the angle of bifurcation. The esophagus is dorsal and to the left.

The bronchi take an oblique course to the hilus of the lung, where they branch. The right bronchus is nearer to the vertical in its course than is the left; it is also shorter and broader. These conditions explain the more frequent entrance of foreign bodies into the right than into the left bronchus. The asymmetrical course of the two bronchi is probably genetically associated with the position of the heart and aorta.

The azygos vein arches over the right bronchus, the vagus passes dorsally, and the right branch of the pulmonary artery crosses ventrally below the level of the first (eparterial) branch of the bronchus. The aorta arches over the left bronchus and gains its dorsal surface along with the esophagus; the left branch of the pulmonary artery passes at first ventrad and then cephalad to the bronchus.

FIG. 1002.—SCHEMATIC LONGITUDINAL SECTION OF THE WALL OF THE TRACHEA. (Gegenbaur.)



Dimensions.—On account of their elasticity considerable difficulty is met with in obtaining accurate measurements of the air-tubes. The length of the trachea is given at 95–122 mm.; its transverse diameter 20–27 mm.; the sagittal diameter 16–20 mm. The right bronchus has a length of 25–34 mm.; the left, 41–47 mm. The transverse diameter of the right is 18 mm.; of the left, 16 mm. The angle of bifurcation of the trachea varies from 56° to 90°, the mean being 70.4°; a wide angle corresponding to the breadth of the thorax of man. The right bronchus makes an angle of 24.8° with the median plane; the left, 45.6°.

According to Tillaux the length of that portion of the trachea between the superior edge of the sternum and the cricoid cartilage varies with age and sex as follows:

Adult male,	from 4.5 to 8.5 cm	average, 6.5 cm.
Adult female,	from 5 to 7.5 cm	average, 6.4 cm.
Boys $2\frac{1}{2}$ to 10 years,	from 2.7 to 6.5 cm	average, 4.4 cm.
Girls $3\frac{1}{2}$ to $10\frac{1}{2}$ years,	from 4 to 6.5 cm	average, 5.1 cm.

The diameter of the lumen of the trachea when distended to a cylindrical form has been measured by Sée as follows: newborn, 4.12 to 5.6 mm.; infant 2 years, 7.5 to 8 mm.; infant 4 to 7 years, 8 to 10.5 mm.; over 20 years, male, 16 to 22.5 mm.; over 20 years, female, 13 to 16 mm.

Structure of the trachea and bronchi (figs. 989, 999, 1000, 1002).—The walls of the trachea and bronchi are composed of a series of cartilages having the form of incomplete rings, held together and enclosed by a strong and elastic fibrous membrane. Dorsally, where the rings are deficient, this membrane remains as the membranous wall [paries membranaceus]; between the cartilages it constitutes the annular ligaments [ligg. annularia (trachealia)].

A tracheal cartilage [cartilago trachealis] comprises a little more than two-thirds of a circle. Its ends are rounded, its outer surface flat, while the inner surface is convex from above downward; the upper and lower margins are nearly parallel. The cartilages are from sixteen to

twenty in number. The first is usually broader than the type, and is connected by the cricotracheal ligament with the cricoid cartilage. Sometimes these two cartilages are in part continuous. The last cartilage is adapted to the bifurcation of the trachea and presents at the middle of its lower margin a hook-like process. This turns backward between the origins of the bronchi, and in the majority of cases gives a cartilaginous basis to the tracheal carina. Some of the tracheal cartilages vary from the type by bifurcating at one end. The cartilages keep the lumen of the trachea patent for the free passage of the air. Calcification occurs as with the laryngeal cartilages, but much later in life.

A **mucous coat** [tunica mucosa], soft and pinkish-white in color, covers the inner surface of the trachea (fig. 1002); posteriorly it is thrown into longitudinal folds. Mucous **tracheal glands** [gl. tracheales] are present in the elastic **submucous coat** [tela submucosa] between the cartilages and at the dorsum of the trachea. A thin layer of transversely disposed smooth muscle-fibers, stretching between the ends of the cartilages in the dorsal wall, constitutes the **muscular coat** [tunica muscularis]. Contraction of this *trachealis muscle*, as it is more properly named, causes the ends of the tracheal cartilages to be approximated and the lumen of the windpipe to be diminished.

The structure of the walls of the bronchi is similar to that of the trachea. The right bronchus possesses six to eight cartilages; the left, nine to twelve.

An inconstant *bronchoesophageal* muscle may connect the back of the left bronchus with the gullet.

Vessels and nerves.—The *arteries* supplying these air-tubes come from the inferior thyroid and from the internal mammary by its anterior mediastinal or bronchial branches. *Venous radicles* come together in the annular ligaments and join lateral veins on either side, which empty the blood into the plexuses of the neighboring thyroid veins.

Lymph-vessels are abundant, and are disposed in two sets, one in the mucosa, another in the submucosa. They drain into the tracheal, bronchial and esophageal lymph-glands. The lymphatics of the tracheal submucosa establish a direct pathway of infection to the lung by anastomosing with periarterial and peribronchial lymphatics at the bifurcation of the trachea (Winternitz). *Nerves* are provided by the vagus direct, by the inferior laryngeal, and by the sympathetic.

THORACIC CAVITY

Thoracic cavity [cavum thoracis] is the term used to denote the space included by the walls of the thorax and occupied by the thoracic viscera. These are, on each side, the lung, the pleura with its cavity, and in the middle the thymus gland or its remains, the pericardium and heart, great vessels, nerves, trachea, thoracic duct and esophagus, all closely associated and surrounded by connective tissue, forming a dividing wall, the mediastinal septum, standing between the right and left sides of the thoracic space.

The **limits** of the thoracic space are given by the skeletal parts of the thorax together with the ligaments involved in the articulations and the muscles and membranes interposed between the bones. The arched diaphragm forms the inferior limit; and the barrier presented by the scalene muscles and the cervical fascia makes the superior boundary, which, it is to be observed, lies above the plane of the superior aperture of the thorax and therefore in the base of the neck (fig. 1003). These boundaries are approached by the extension of the pleural cavities; yet there intervenes the parietal layer of the pleural sac which is connected with the thoracic walls by loose connective tissue, the **endothoracic fascia.**

The **form** of the thoracic space departs from the external contour of the thorax chiefly through the projection into it of the ridge made by the succession of the thoracic vertebral centra, and by the presence on either side of the latter of the broad, deep pulmonary sulcus. On account of these features a transverse section of the thoracic space is somewhat heart-shaped, however, much compressed ventrodorsally (fig. 1009).

The arch of the diaphragm on the right side rises to the level of the spinous process of the seventh thoracic vertebra; on the left, to the level of the eighth thoracic spinous process. At its circumference the diaphragm is in contact to a variable extent above its origin with the inner surfaces of the costal arches. In the lower part of this zone a connection exists between the muscle and the thoracic wall through a continuation of the endothoracic fascia; in the upper part, the phrenicocostal sinus (see p. 1260) intervenes. The level reached by this deepest part of the pleural cavity is lower than the summit of the peritoneal cavity, so they overlap to a considerable extent.

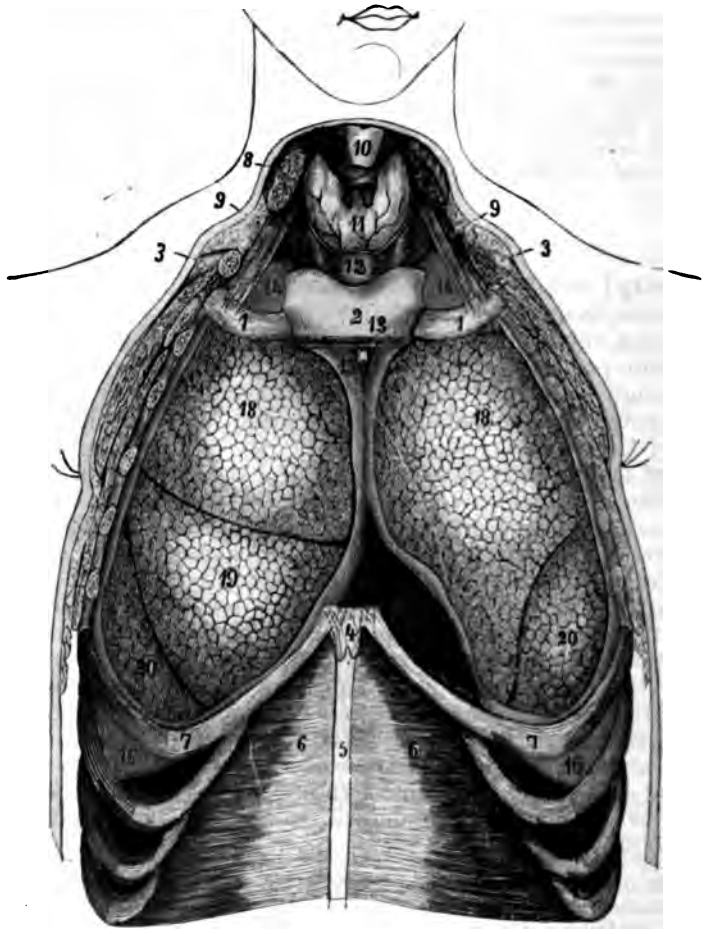
THE PLEURÆ

The **pleuræ** (figs. 1003, 1009) are the paired, closed serous sacs which invest nearly the whole surface of the lungs forming the **pulmonary pleuræ**, and in large measure line the inner surface of the thoracic walls, forming the **parietal pleuræ.** Strictly speaking, however, the *endothoracic fascia* lines the thoracic cavity, and

the pleuræ together with other structures are contents of the thoracic cavity. The right and left pleural sacs are completely separated one from another by a sagittal partition, the *mediastinal septum* (see p. 1261). The walls of the sacs enclose paired spaces or cavities known as the **pleural cavities**, which in the normal state are merely potential or capillary spaces containing a small amount of serous fluid for lubrication of the apposed surfaces of the pulmonary and parietal pleuræ. The right and left pleural cavities, as the pleural sacs, are absolutely independent of each other, are lined by endothelium and present a smooth glistening appearance.

FIG. 1003.—PLEURAL CAVITY OPENED FROM IN FRONT.

1, first rib; 2, manubrium sterni; 3, acromial extremity of clavicle; 4, xiphoid process; 5, linea alba; 6, m. transversus abdominis; 7, seventh rib; 8, sternocleidomastoid m.; 9, anterior scalene m.; 10, larynx; 11, thyroid gland; 12, deep layer of cervical fascia in front of the trachea; 13, superior mediastinum; 14, pleural cupola; 15, mediastinal pleura (costomediastinal sinus) 16, lower margin of costal pleura (phrenicostal sinus); 17, pericardium; 18, superior lobe of lung; 19, middle lobe of right lung; 20, inferior lobe of lung; 21, diaphragm. (Rauber-Kopsch.)

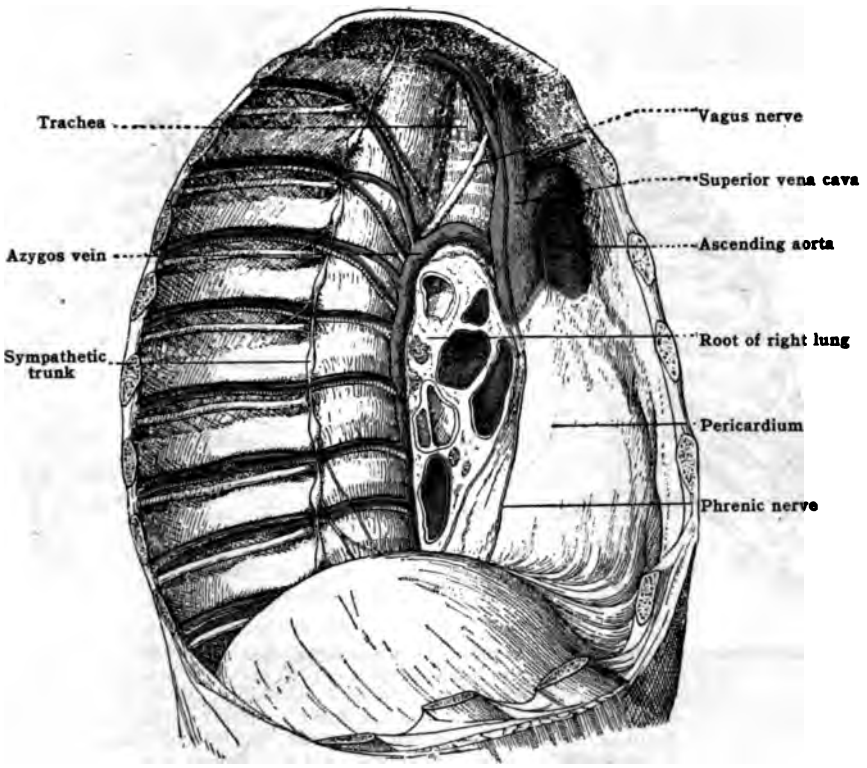


The paired **pulmonary pleura** covers the outer surface of the lung, with which it is inseparably connected. It follows all irregularities of the lung surface and dips into the fissures of the lung so as to separate the lobes. At the hilus the pulmonary pleura passes from the mediastinal surface of the lung to cover the root above, in front, and behind, then continues medialward as the mediastinal portion of the parietal pleura, forming caudal to (below) the root of the lung a double layer of mediastinal pleura which is directed caudalward and medialward as the **pulmonary ligament** (fig. 1010). The portion of the lung occupied by the hilus and the very limited space of the lung surface between the layers of the pulmonary ligament caudal to the hilus have no pleural investment.

The paired **parietal pleura** is divided, according to the regions of the chest with which it is associated, into the *costal*, *diaphragmatic*, and *mediastinal pleuræ;* moreover, the parietal pleura extends into the root of the neck, forming the *cervical pleura* [*cupula pleuræ*]. It must be kept in mind that the subdivision of the parietal pleura as indicated is more or less arbitrary and that the several divisions are directly continuous with each other.

The **costal pleura** lines the thoracic wall, to which it is loosely bound by the *endothoracic fascia;* dorsally where the pleura is reflected from the ribs to the vertebral column, it is more firmly atached. It covers incompletely the deep surface of the sternum and extends laterally upon the inner surfaces of the ribs and intercostal muscles. Dorsally beyond the angles of the ribs it passes over the anterior rami of the thoracic nerves and intercostal vessels, the heads of the ribs, and the sympathetic trunk to the vertebral column; here it becomes continuous with the mediastinal pleura. Above (cranialward), the costal pleura reaches beyond the superior aperture of the thorax into the root of the neck, and in the form of a dome, the **cupola** of the pleura,

FIG. 1004.—RIGHT LATERAL SURFACE OF THE MEDIASTINUM AFTER REMOVAL OF THE PLEURA. (Poirier and Charpy.)



is adapted to the apex of the lung. It is supported by processes of the deep cervical fascia, and by a fibrous aponeurosis known as *Sibson's fascia*, coming from the scalenus minimus muscle and connected with the inner margin of the first rib. In relation to the pleural cupola are those structures grouped about the lung apex: the brachial plexus, subclavian artery, anterior scalene muscle, and the subclavian vein, and, on the left side, in addition, the thoracic duct. The highest point dorsally of the cervical pleural dome reaches the neck of the first rib; ventrally from 3 to 6 cm. above the sternal end of the first rib, and from 1 to 4 cm. above the clavicle. Below (caudalward), the costal pleura is continuous with the **diaphragmatic pleura** [pleura diaphragmatica], which is bound closely by a very sparse endothoracic fascia to the thoracic surface of the diaphragm and covers it, excepting the pericardial area and where the diaphragm and thoracic wall are in contact.

The **mediastinal pleuræ** are reflected from the costal pleuræ on the deep surface of the sternum, at the right and left sides of the mediastinum as the **laminæ mediastinales,** covering the pericardium [pleura pericardiaca], to which they are closely adherent, and also the other structures of the mediastinum, with which the two layers are less firmly connected. Above (cephalad to) the lung root each mediastinal pleura stretches directly from the sternum to the vertebral column; at the level of the root it is reflected laterally to the pulmonary pleura covering the root ventrally and dorsally, while caudal to the root the mediastinal pleura forms a double layer—the *pulmonary ligament.* The right mediastinal lamina covers (fig. 1004) the right innominate vein, the superior vena cava, the vena azygos, the trachea, the innominate artery,

the description of the reflections of the parietal pleuræ, the ventral mediastinal space is narrow cephalically, due to the close approximation in the midline of the right and left mediastinal pleuræ. This takes place on the ventral aspect of the pericardium from the sternal angle to the fourth costal cartilages. Owing to the receding of the left mediastinal pleura from the midplane and from its fellow, the ventral mediastinum is of considerable but variable breadth in its lower or caudal half. The components of the ventral mediastinum are the caudal portion of the thymus, a few lymph-nodes, lymph-vessels, adipose and areolar tissue, and small branches from the internal mammary arteries.

The **middle mediastinum** is the expanded central portion of the caudal segment of the mediastinal septum. It is, generally speaking, coextensive with the pericardium and in addition to the latter consists of the heart, the ascending aorta, the trunk of the pulmonary artery, the cardiac end of the superior vena cava, the arch of the azygos vein, the phrenic nerves and accompanying vessels, the bronchial lymph-nodes, and a large portion of the roots of the lungs.

The **posterior** (dorsal) **mediastinum** (fig. 1009) occupies the interval bounded by the lower eight thoracic vertebræ dorsally; the pericardium and the roots of the lungs ventrally; the mediastinal pleuræ laterally. It extends from the fourth thoracic vertebra to the diaphragm. It may be thought of as a caudal extension of the more dorsal portion of the superior mediastinum, many of the component structures of the latter being prolonged into the dorsal mediastinum on their way to the abdominal cavity. The dorsal mediastinum includes the esophagus, the descending thoracic aorta and its right intercostal branches, the azygos and hemiazygos veins and tributaries, the thoracic duct, the vagi and splanchnic nerves, and the dorsal mediastinal lymph-nodes; all surrounded and supported by connective tissue.

THE LUNGS

The **lungs** [pulmones], the essential organs of respiration, are constructed in such a way as to permit the blood to come into close relation with the air (fig. 1008). In plan of structure the lung has been compared with a gland, since it is

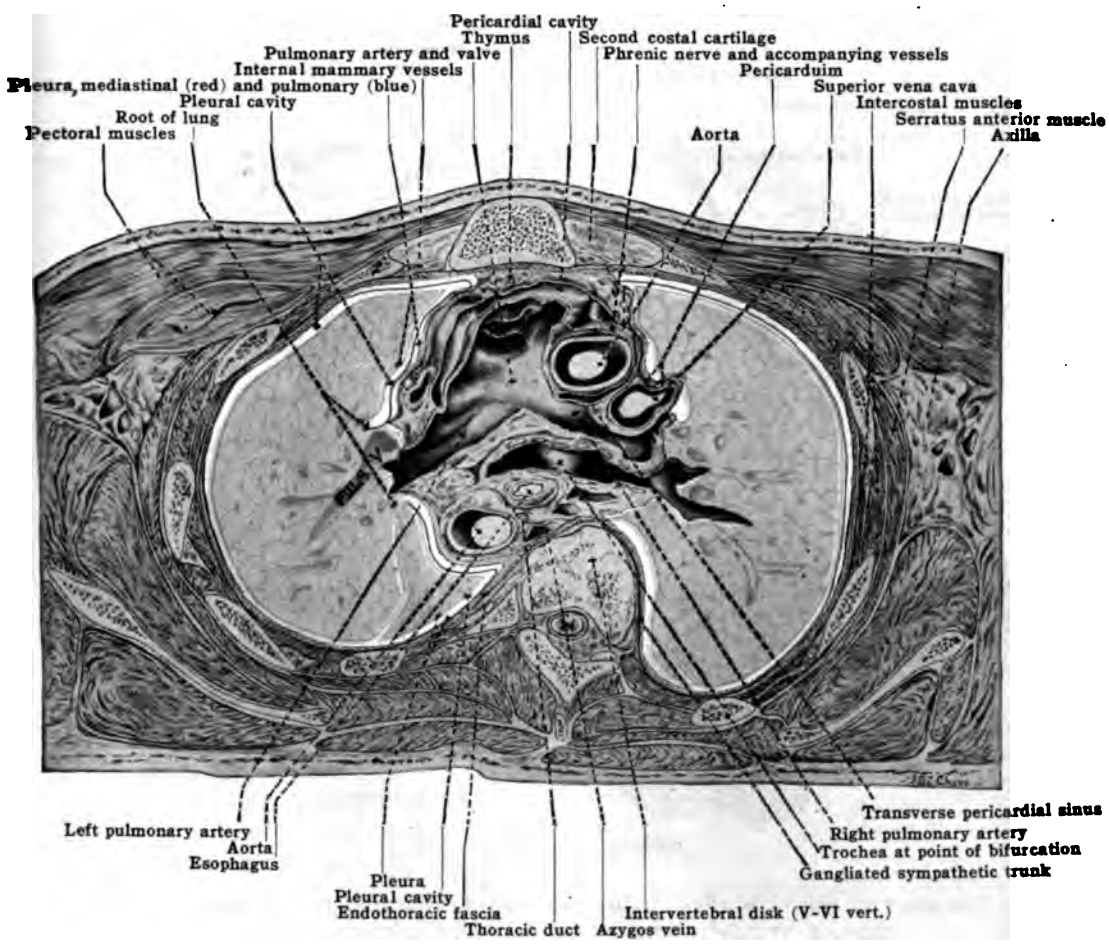
composed of a tree-like system of tubes terminating in expanded spaces. Closely associated with the system of tubes are certain blood-vessels, some nutritive but most of them respiratory in character.

The lungs are two in number, and lie one on either side of the thoracic cavity separated by the mediastinal partition (figs. 968, 1009). Serous membranes covering the latter right and left are parts of two closed sacs, the **pleuræ**, each of which is to be regarded as lining one lung and the neighboring chest-wall after the manner of serous membranes in general. The spaces enclosed within the sac-walls are the **pleural cavities**, potentially subdivisions of the cœlom. It must be kept clearly in mind that the lungs are not contained within the pleural cavities (p. 1258), but lie in pleural cavities containing a small amount of serous fluid.

Form of the lungs (figs. 1009, 1010).—Each lung is pyramidal or conical in form, with the **base** [basis pulmonis] caudal and resting on the diaphragm, and with **apex** [apex pulmonis] cephalic, in the root of the neck. Three surfaces, costal, mediastinal and diaphragmatic are described. The broad convex **costal surface** [facies costalis] is directed against the thoracic wall ventrally, laterally and dorsally, and is marked by grooves corresponding to the ribs. The **mediastinal surface** [facies mediastinalis] is concave and presents a contour adapted to structures of the mediastinum (fig. 1010). A special concavity on this surface, known as the **cardiac fossa,** corresponds to the prominence of the heart and is deeper in the left lung than in the right. Above and behind the cardiac fossa

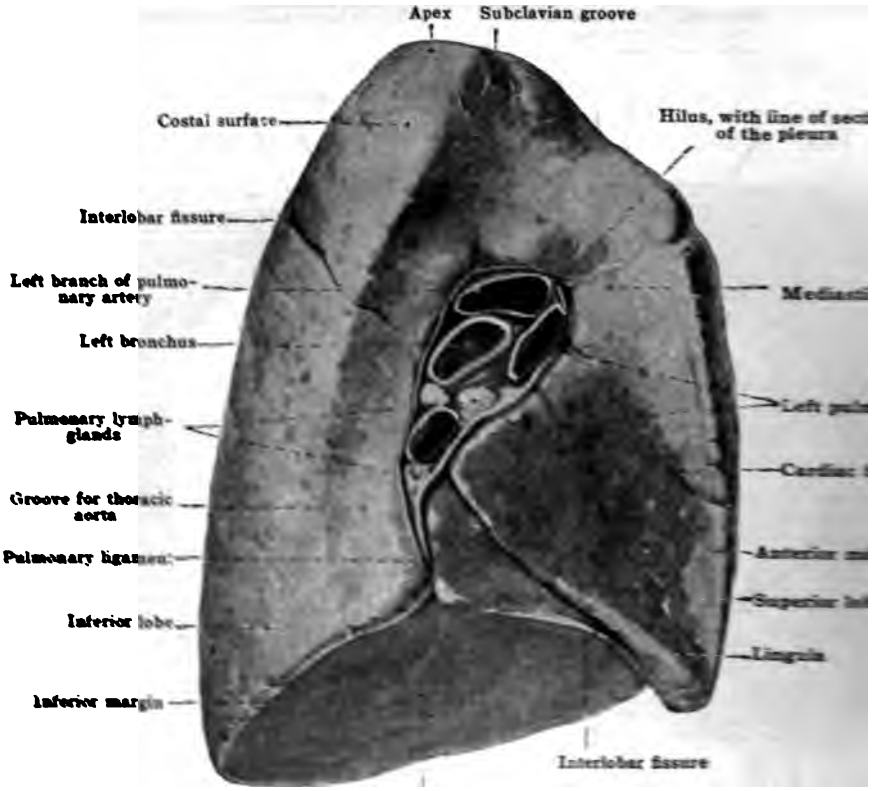
FIG. 1009.—HORIZONTAL SECTION OF THE THORAX THROUGH THE ROOTS OF THE LUNGS.



is a depression, the **hilus** of the lung [hilus pulmonis], where the bronchus, pulmonary vessels, lymphatics and nerves, together constituting the **root** of the lung [radix pulmonis], enter and leave. Near the dorsal edge of the mediastinal surface is a groove, which ascends and turns forward over the hilus. The groove of the left lung is adapted to the cylindrical surface of the aorta; that of the right, the vena azygos. A well-marked **subclavian sulcus** extends upward on this surface to the apex, corresponding on the right side to the lower part of the trachea and right subclavian artery, on the left to the left subclavian artery alone. Further forward is a groove adapted in the right lung to the superior cava; in the left to the left innominate vein. The lung with its visceral pleura is not in actual contact with these several structures, but is separated from them by the pleural cavity and the mediastinal pleura. The mediastinal surface passes gradually into the costal surface dorsally, there being no proper dorsal edge. Where the mediastinal and costal surfaces meet ventrally, a sharp ventral or **anterior margin**

phragm and thoracic wall.

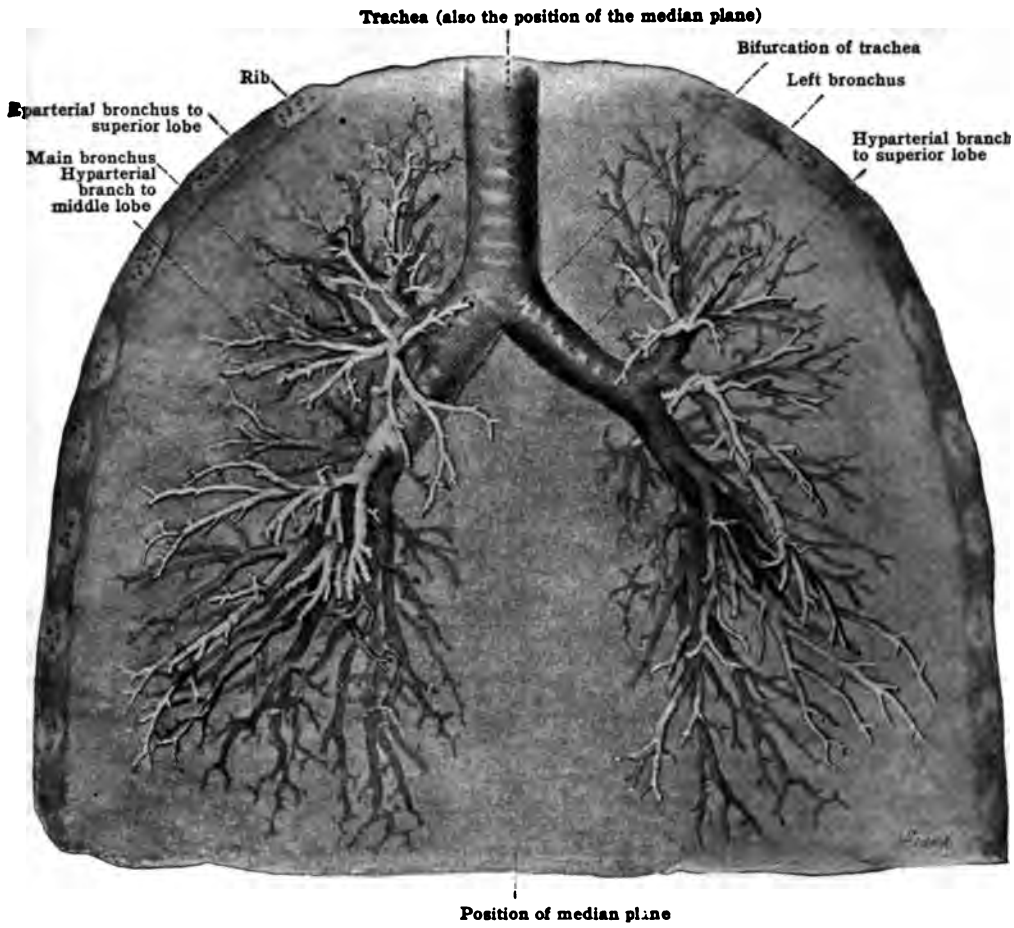
FIG. 1010.—LEFT LUNG, VIEWED FROM THE MEDIASTINAL SURFACE. (Spalteh



The **apex** of the lung [illegible] is rounded and points

inferior lobe [lobus inferior]. The interlobar fissure runs caudally and ventrally beginning a short distance below the apex, and reaching the base near the anterior margin in the left lung, somewhat further back in the right lung. From the obliquity of the plane of the fissure it will be noticed that the inferior lobe reaches dorsally to within a short distance of the apex, and includes the greater part of the back and base of the lung, while the superior lobe takes in the anterior margin and apex. The presence of a **middle lobe** [lobus medius] disturbs the symmetry of the right lung. This results from a deep, nearly horizontal **secondary fissure** cutting through the lung somewhat below its middle, and extending along the plane of the fourth rib between the anterior margin of the lung and the main interlobar fissure, which it reaches at about the level of the midaxillary line.

FIG. 1011.—CAST OF THE AIR-TUBES AND THEIR BRANCHES, VIEWED FROM IN FRONT. (Spalteholz.)



Besides possessing the individual peculiarities mentioned, the two lungs further differ from each other in general form and weight, the right lung being considerably broader and heavier than the left. The difference in length maintained by some anatomists, even if it prove constant, must be slight and of little practical importance. These differences seem to follow the asymmetry of the vault of the diaphragm and the position of the heart.

Topography of the lungs.—The **apices** of the lungs extend upward as high as the first thoracic vertebra, a level considerably higher than the superior margin of the sternum (figs. 1013, 1014). The subclavian vein and artery and the brachial plexus, together with the anterior scalene muscle, control to a certain degree the height reached. There seems to be no constant difference between the levels attained by the apices of the two lungs. The extent to which the apex rises above the clavicle is rarely more than 3.5 cm. (Merkel), and will, of course, vary with individual differences in the position and form of this bone. The average is not over 2.5 cm. (1 in.).

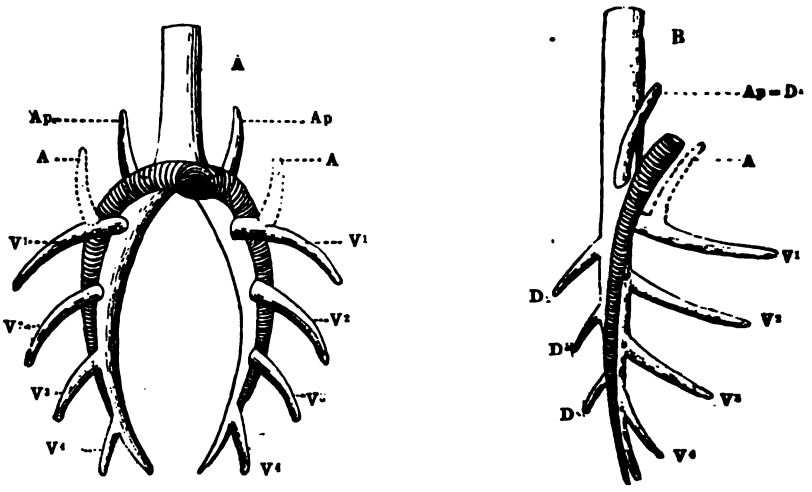
The **base** of the lung, resting on the diaphragm, is separated by that thin partition from the underlying abdominal viscera: thus beneath the base of the right lung is the right lobe of the

liver, while under the left lung are the left lobe of the liver, the fundus of the stomach, and the spleen. The position of the apex changes very little in respiration, and the same holds true for the dorsal bulky part of the lung. In deep inspiration the thin inferior (caudal) and anterior (ventral) margins of the lung migrate into and partially obliterate the phrenicocostal and the costomediastinal sinuses of the pleura, respectively. The dorsal part of the lung rests against the side of the vertebral column in the deep hollow of the angles of the ribs, and reaches below to the level of the eleventh costovertebral joint (fig. 1014).

The anterior margins (fig. 1013) descend in curves from behind the sternoclavicular joints and run near together a little to the left of the median line. At the level of the sixth costosternal junction the anterior margin of the right lung turns lateralward to follow the sixth costal cartilage. The anterior margin of the left lung turns lateralward along the fourth costal cartilage as far as the parasternal line, descending in a curve to the lingula and thus forming the cardiac incisure. The positions of the inferior margins (figs. 1013. 1014) of the two lungs are practically alike in their positions. Each extends in a curve convex downward, behind the sixth costal cartilage in its entire length, crosses the costochondral junction of the sixth rib to

FIG. 1012.—SCHEME OF THE BRONCHIAL TREE ACCORDING TO NARATH. A. Anterior view. B. Right lateral view. (Poirier and Charpy.)

A. Apical bronchus, collateral of the first ventral and susceptible of becoming eparterial. Ap. in migrating to the bronchial trunk.



the superior margin of the eighth rib in the axillary line, and so to the ninth or tenth rib in the scapular line, whence they run horizontally medialward to the eleventh costovertebral joint. These relations are the mean between the conditions observed in the cadaver and as found by physical examination of the living. In old age the inferior margins of the lungs reach a level one or two intercostal spaces lower than is the case in adult life (Mehnert).

The chief or interlobar fissure (fig. 1014) begins dorsally about 6 cm. below the apex of the lung at the level of the head of the third rib. With the arm hanging at the side, a line drawn across the back from the third thoracic spine to the root of the scapular spine would indicate the course of the upper part of this fissure. (Merkel.) Thence it passes caudalward and around the chest to the end of the sixth rib in the midclavicular (mammillary) line. Merkel points out the use of the root of the scapular spine as a landmark for finding the limits of the lobes dorsally: with the arm hanging at the side all above this spot is superior lobe; all below it the inferior. The secondary fissure of the right lung begins at the main interlobar fissure in the midaxillary line, about the level of the fourth rib or fourth interspace, and passes nearly horizontally to the anterior margin of the lung at the level of the fourth rib.

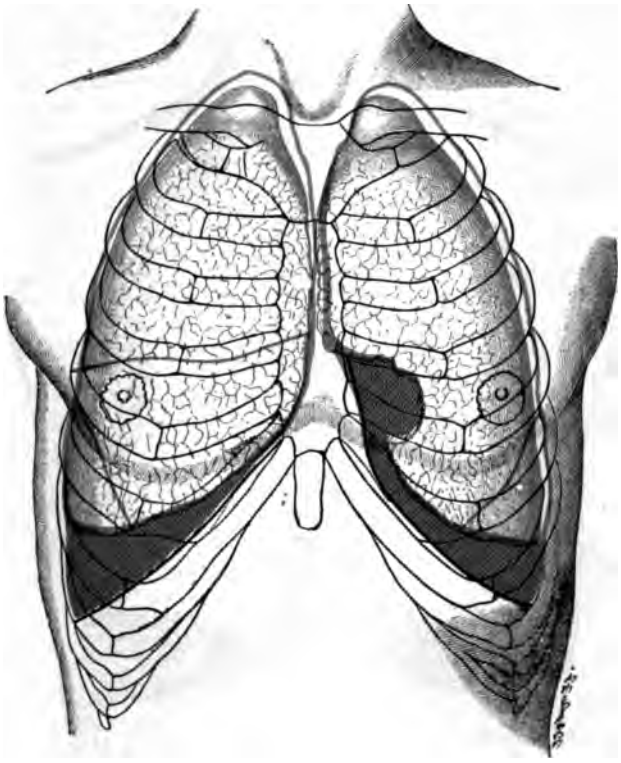
The roots of the lungs are placed opposite the fifth, sixth, and seventh thoracic vertebræ. The right root lies dorsal to the superior vena cava and under the arch of the azygos vein; the left root is beneath the aortic arch and ventral to the thoracic aorta. The phrenic nerve passes ventrad to each root, the vagus dorsad. The pulmonary plexuses occupy ventral and dorsal positions, respectively. The pulmonary ligament of the pleura goes from the caudal edge of the root (see p. 1260).

Branching of the bronchial tubes (figs. 1000, 1011).—Each bronchus, from its origin at the bifurcation of the trachea, takes an oblique course to the hilus, and then continues in the lung as a main tube, extending toward the posterior part of the base. These stem-bronchi are curved, probably in adaptation to the heart, the right like the letter C and the left like an S. Throughout their course the stem-bronchi give off in monopodic fashion collateral branches, the bronchial rami [rami bronchiales], and these, branching in a similar way, reach all parts of the lung.

The first bronchial ramus of the right stem-bronchus arises above the place where the latter is crossed by the pulmonary artery and is named the **eparterial bronchial ramus** [ramus bronchialis eparterialis]; it supplies the superior lobe of the right lung, sending a special branch to the apex. All other bronchial rami, whether in the right or left lung, take origin from the stem-bronchi below the level of the crossing of the pulmonary artery and are called **hyparterial bronchial rami** [rami bronchiales hyparteriales]. The second bronchial branch of the right lung goes to supply the middle lobe, while several bronchial branches enter the inferior lobe. On the left side, the first bronchial branch arises below the crossing of the pulmonary artery, and goes to supply the superior lobe, providing it with an apical ramus. The other branches are given to the inferior lobe.

Structure of the bronchial rami.—The larger bronchial rami contain in their walls both C-shaped and irregular plates of cartilage, the latter gradually replacing the former as the branches become smaller. The membranous wall is lost and plates of cartilage are disposed on all sides. The mucosa,with ciliated epithelium, is thrown into longitudinal folds covering

FIG. 1013.—VENTRAL TOPOGRAPHY OF THE LUNGS AND PLEURA. (After Merkel.)



bundles of elastic fibers of the membrana propria. Next to the latter is a continuous layer of smooth muscle-fibers circularly arranged. Mucous secreting **bronchial glands** [gl. bronchiales] are present as far as tubes of 1 mm. diameter; here the cartilages also disappear.

To W. S. Miller is due the credit of having greatly increased our knowledge of the finer structure of the lung and for having presented the conception of the primary lung lobule now generally accepted by anatomists. Some of the chief results of Miller's work are embodied in the following descriptions pertaining to the termination of the air-tubes and to the blood and lymph vascular systems of the lungs and pleura.

Through further branching of the bronchial rami a great number of very fine **bronchioles** [bronchioli] are reached, whose walls possess a weak muscle layer and are lined by mucosa having an epithelium of flattened non-ciliated cells. These, subdividing, give rise to the **respiratory bronchioles** [bronchioli respiratorii], the walls of which are beset with alveoli (fig. 1008). From the respiratory bronchioles arise the **alveolar ducts** [ductuli alveolares], or terminal bronchi, each of which leads to a group of air-spaces, called *atria*, each of which again communicates with a second series of air-spaces, the *air-sacs* (alveolar sacs or infundibula), whose walls are pouched out to form numerous **pulmonary alveoli** [alveoli pulmonum].

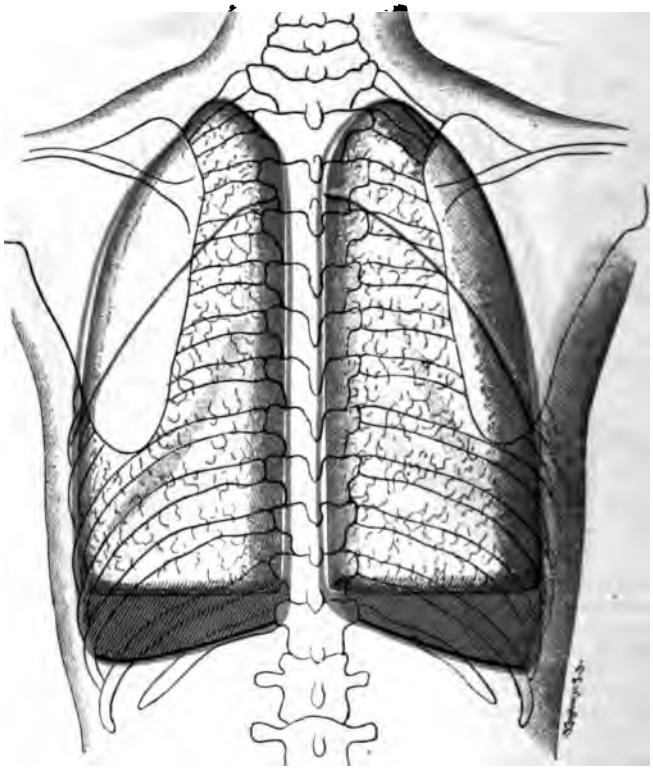
A terminal bronchus with its air-spaces and blood-vessels, lymphatics and nerves, together form a **pulmonary lobule** [lobulus pulmonum], the unit of lung structure.

Aeby divided the bronchial branches into two sets, according to their relation to the pulmonary artery. The branch arising above the place where the pulmonary artery crosses the stem-bronchus he named the **eparterial bronchus,** and those arising below the crossing he called **hyparterial.** An eparterial bronchus exists only on the right side; all other branches are hyparterial. Since the eparterial supplies the superior lobe of the right lung and no eparterial

branch is present on the left side, Aeby concluded that the left lung had no lobe homologous with the superior lobe of the right lung. He compared the middle lobe of the right with the superior lobe of the left lung. The collateral branches of the stem-bronchi arise in a dorsal and ventral series in the lower mammals, and the same arrangement, though less obvious, obtains in man. According to the views of Aeby and Hasse, the first ventral branch of the right side is distributed to the middle lobe, while the remaining three ventral and all the dorsal lateral branches are given to the inferior lobe. On the left side, the first ventral branch is given to the superior lobe; the other ventral branches and the dorsal branches are distributed to the inferior lobe.

Narath is not in accord with Aeby and considers the division of bronchial branches in accordance with their relation to the pulmonary artery as of no great morphological significance. He attributes the apparent differences on the two sides to a shifting in position of homologous branches. Thus, Narath considers that the eparterial bronchus of Aeby has become the first dorsal lateral branch by displacement above the pulmonary artery and that it is homologous

FIG. 1014.—DORSAL TOPOGRAPHY OF THE LUNGS AND PLEURA. (After Merkel.)
The parietal pleura is in green, visceral pleura and lungs in red, lung fissures in blue.



with an apical branch of the left side, which retains its primitive origin from the first ventral branch (fig. 1012). Huntington in extensive studies of the bronchial tree in mammals supports the conclusions of Narath, believing that the eparterial bronchus is a secondary branch which has migrated cephalically on the main stem. Since the designation 'epiarterial' connotes a faulty morphology Huntington argues that, except for purposes of topography, we should abandon the distinction between eparterial and hyparterial bronchi.

The physical properties of the lungs.—The average *dimensions* in the adult male are as follows: Height of the lung is given at 25–27 cm., the greatest sagittal diameter at 16–17 cm., and the greatest transverse measurement as 10 cm. for the right and 7 cm. for the left. The *volume* of the lungs when well expanded is 6500 c.c. (Merkel.) The *weight* of the lungs can be found only approximately on account of the presence of blood and mucus. In the adult male the weight of both lungs is given as 1300 gm.; female, 1023 gm. The weight of the right lung compared with the left is as 11 is to 10. Ried and Hutchinson found the weight of the lungs compared with that of the body as 1 : 37 (male), 1 : 43 (female); in the fetus at term, 1 : 70. After respiration has been established, the lung, if placed in water, will float. Its *specific gravity* is between 0.345 and 0.746. (Rauber.) The fetal lung contains no air and is heavier than water. Its specific gravity is 1.045 to 1.056. (Krause.) Lung tissue, free of air, with vessels moderately filled, has likewise a specific gravity of 1.045 to 1.056. (Vierordt.)

The color of the lung results from the presence of blood, pigment, and the air in the alveoli. It varies, therefore, as these constituents are all or in part present and with differences in their proportions. Thus the general color is red in the fetus, pink in the infant, and gray mottled

with black in the adult. The dark color is traceable to the carbonaceous matter carried into the lungs from the atmosphere.

In consistence the lung is soft and spongy, and when compressed between the fingers, emits a crackling sound. Among the physical properties the elasticity of the lung is quite remarkable. Under ordinary conditions the pressure of the air in the lung keeps the alveoli and the organ as a whole distended, but when the pleura has been opened and the air pressure equalized without and within, the lung collapses.

Vessels and nerves of the lungs.—The **bronchial arteries** (see p. 624), belonging to the systemic system, carry blood for the nourishment of the lungs. They arise from the aorta or from an intercostal artery, two for the left lung and one for the right, and, entering at the hilus, reach the dorsal wall of the main bronchus. The bronchial arteries accompany the bronchi, whose walls they supply, as far as the distal ends of the alveolar ducts, beyond which they do not go. These vessels also supply the lymph-glands of the hilus, the walls of the large pulmonary vessels, and the connective-tissue septa of the lung. **Bronchial veins** (see p. 699), anterior and posterior, arise from the walls of the first two or three divisions of the bronchi and end in the innominate and the azygos or in one of the intercostal veins; those arising from the walls of the smaller tubes, including the alveolar ducts, join the pulmonary veins. The **pulmonary artery** (see p. 570), entering the hilus in a plane anterior to the bronchus (fig. 1009), turns to the posterior aspect of the main-stem, following its branches and their subdivisions of the lobules. Entering the lobule, the last branch of the vessel gives off as many twigs as there are atria (fig. 1008), and these twigs end in dense capillary nets in the walls of the alveoli. Here the venous blood brought by the pulmonary artery, separated from the air in the alveolus only by a thin septum, is changed to arterial blood in the respiratory process. According to Miller, anastomosis between the branches of the pulmonary artery is exceptional. Anastomosis between the bronchial and pulmonary arteries has been claimed, but the connection apparently existing between these vessels is through the radicles of the bronchial veins which join the pulmonary veins. The pulmonary venous radicles begin at the capillary networks and drain the arterial blood into the pulmonary veins, which run between adjacent lobules and which receive also blood coming from the capillary network of the pulmonary pleura and from the capillary network of the bronchi (fig. 1008). Thus it will be seen that while the pulmonary vein carries mainly arterial blood, it carries also some venous blood. The **pulmonary veins** (see p. 570) follow the bronchial tree on the side opposite the arteries to the hilus, where, having converged to two large trunks located in the root of the lung below the plane of the artery, they pass to the left atrium. The pulmonary veins have no valves.

Lymphatics.—Miller has found the lymphatic vessels forming a closed tube system in the walls of the bronchi, in the pleura, and along the branches of the pulmonary artery and veins. Within the lung numerous **pulmonary lymph-glands** [lymphoglandulæ pulmonales] are found chiefly at the places of branching of the larger bronchi [lymphoglandulæ bronchiales]. Scattered along the latter, as well as associated with the branches of the pulmonary artery and vein, are found nodules of lymphoid tissue. Deposits of carbonaceous matter in the lymphoid structures of the lung are present, except in early infancy; the amount increases with age.

Nerves.—The vagus and sympathetic contribute to form the pulmonary plexuses in front and behind the root of the lung, from which branches go to accompany bronchial arteries; a smaller number accompany the air-tubes (see p. 1073).

Variations.—Congenital absence of one or both lungs has been observed. Variations in the lobes are not uncommon—four for the right and three for the left lung has been recorded. An *infracardiac lobe*, as found in certain mammals, sometimes occurs; an infracardiac bronchus is, however, constant in man. More or less complete fusion of the middle and upper lobes of the right lung is not rare.. The lungs may be symmetrical, with two lobes each, the apical bronchus of the right springing from the first ventral bronchus, as is normal for the left lung (Waldeyer, Narath); or the lungs may have three lobes each, the apical bronchus of the left arising from the main bronchus. The apical bronchus of the right lung may arise from the trachea, an origin that is normal in the hog and other artiodactyls.

Development of the lungs and trachea.—The first indication of the trachea and lungs appears in embryos of the third week as a trough-like groove in the ventral wall of the upper part of the esophagus, communicating above with the pharynx. Later the groove becomes constricted off from the esophagus, the constriction extending from below upward, so that a tube is formed which opens into the pharynx above. For further details, see DEVELOPMENTAL ANATOMY, p. 47.

SECTION XII

UROGENITAL SYSTEM

REVISED FOR THE SIXTH EDITION

BY ALBERT C. EYCLESHYMER, B.S., PH.D., M.D.

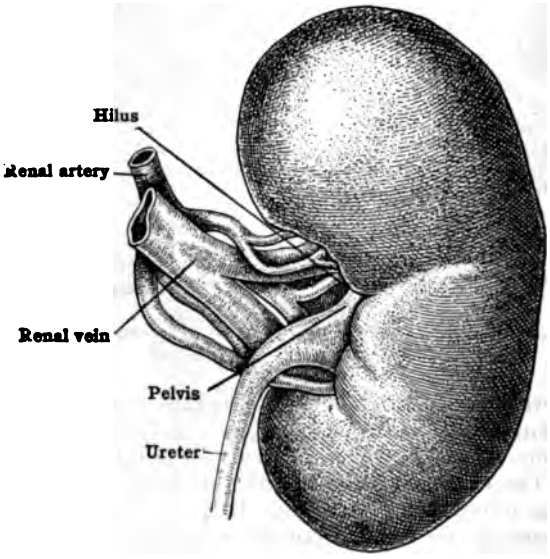
PROFESSOR AND HEAD OF THE DEPARTMENT OF ANATOMY IN THE UNIVERSITY OF ILLINOIS

The **urogenital system** [apparatus urogenitalis] includes (A) the **urinary organs** [organa uropoëtica] and (B) the **reproductive organs** [organa genitalia].

A. THE URINARY ORGANS

THE organs forming the urinary apparatus are the **kidneys,** by which the urine is produced; a duct, the **ureter,** proceeding from each kidney and conveying the urine to the **bladder,** which serves as a reservoir for the urine and from which, by a single duct, the **urethra,** the urine is carried to the exterior.

FIG. 1015.—POSTEROMEDIAL ASPECT OF THE RIGHT KIDNEY.



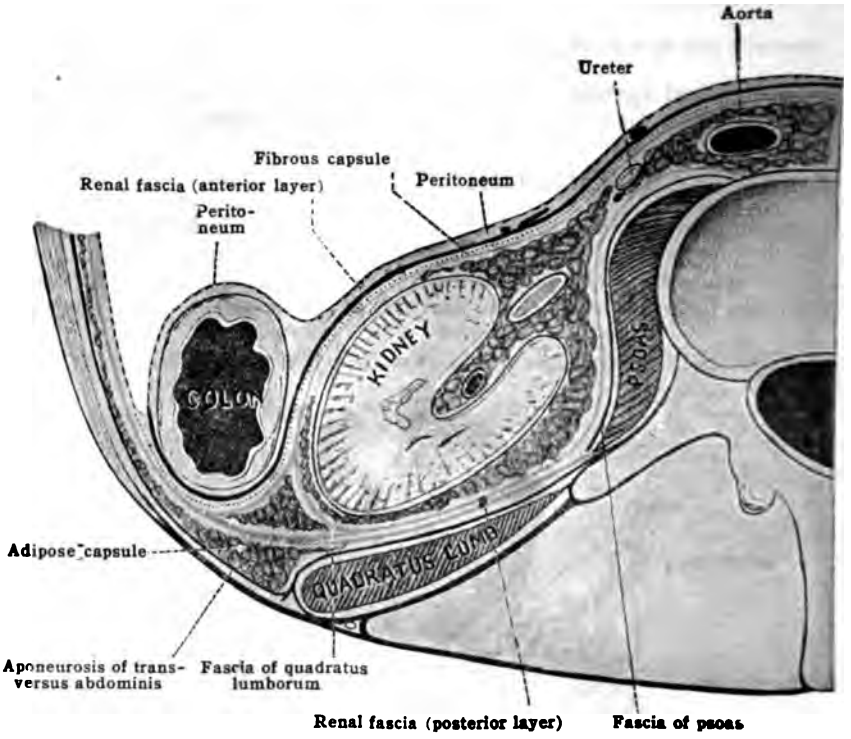
THE KIDNEYS

The **kidneys** [renes] are paired organs situated in the posterior part of the abdomen, on either side of the vertebral column and behind the peritoneum. The right kidney is as a rule, lower than the left. Each kidney is somewhat bean-shaped (fig. 1015) and is situated in such a way that the *ventral* or *visceral surface* [facies anterior] which is convex, looks obliquely ventrally and laterally, while the *dorsal* or *parietal surface* [facies posterior], usually less convex, looks dorsally and somewhat medially (fig. 1016). The *upper extremity* [extremitas superior] is usually larger than the *lower extremity* [extremitas inferior], and is about 1 cm. nearer the vertebral column. The *lateral border* [margo lateralis] is narrow and convex, and the *medial border* [margo medialis], which looks medially and ventrally, is concave, its middle third presenting a slit-like aperture, the **hilus.** This opens

into a cavity, called the **sinus** (fig. 1017), which is about 2.5 cm. in depth and is occupied mainly by the dilated upper extremity of the ureter, known as the renal pelvis, the interval between this and the actual kidney substance containing adipose tissue in which are imbedded the renal vessels and nerves.

Size.—The length of the kidney in the male averages 10–12 cm., its breadth about 5.5 cm. and its thickness 3 cm.; it weighs 115–150 grams. The dimensions of the female kidney are nearly as great, but its weight is from one-seventh to one-fifth less. In the child the organ is relatively large, its weight compared with that of the entire body being about 1 : 133 at birth; but its permanent relation, which is about 1 : 217, is usually attained at the end of the tenth year.

FIG. 1016.—DIAGRAM SHOWING RELATION OF KIDNEY TO CAPSULE AND ADJACENT STRUCTURES. (Gerota.)



Investment and fixation.—The surface of the kidney is covered by a thin but strong *fibrous capsule* [tunica fibrosa]. The capsule divides in the region of the hilus into two layers, one of which turns inward at the hilus to line the walls of the sinus (fig. 1017). The other forms a sheath covering the vessels and nerves before they pass into the hilus. It may readily be peeled off from a healthy kidney, except at the bottom of the sinus, where it is adherent to the blood-vessels entering the kidney substance and to the terminal portions of the pelvis. External to the capsule is a quantity of fat tissue, the **adipose capsule** [capsula adiposa], which forms a complete investment for the organ and is prolonged through the hilus into the sinus.

The *peritoneum*, which covers the ventral surface of the adipose capsule, has usually been regarded as the principal means of fixation of the kidney, but in reality this is accomplished by means of a special **renal fascia** (fig. 1016), developed from the subperitoneal areolar tissue (Gerota).

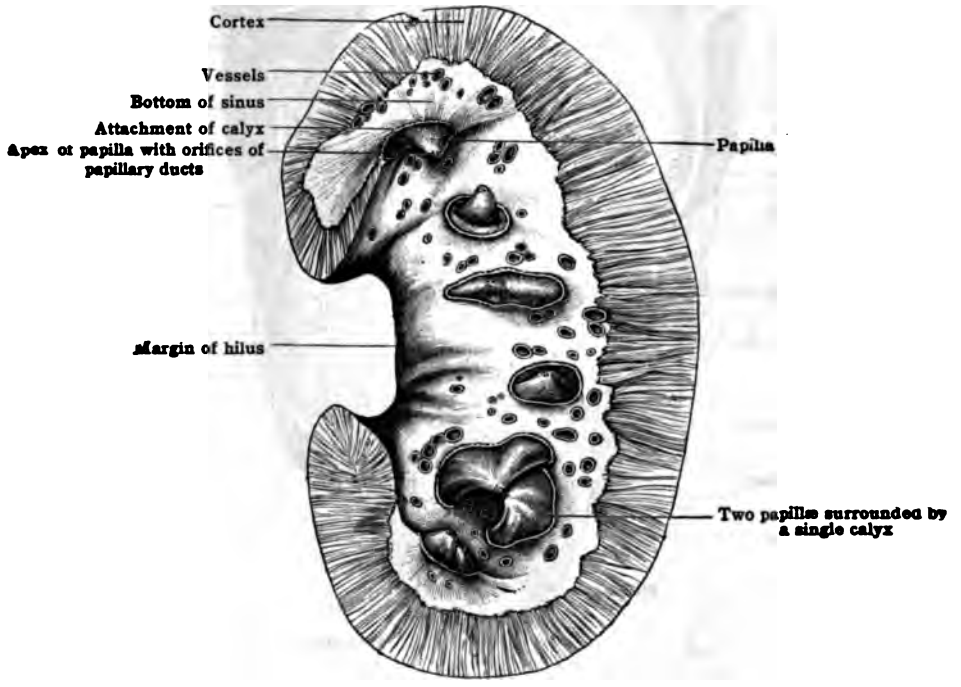
Renal fascia.—Lateral to the kidney there occurs between the transversalis fascia and the peritoneum a subperitoneal fascia, which, as it approaches the convex border of the kidney, divides into two layers, one of which passes in front of and the other behind the kidney, enclosing the adipose capsule. Traced medially, the anterior layer of the renal fascia passes in front of the renal vessels, and, over the aorta, becomes continuous with the corresponding layer of the opposite side; upward, it passes over the suprarenal gland and at the upper border of that organ becomes continuous with the posterior layer; and downward, it is lost in the adipose tissue intervening between the iliac fascia and muscle. The posterior layer, which is the thicker

of the two, passes medially behind the renal vessels and is lost in the connective tissue in front of the vertebral column, and below it is lost, like the anterior layer, in the iliac region. Behind the posterior layer, between it and the quadratus lumborum, is a mass of adipose tissue, the **pararenal adipose body**, and both layers are united to the fibrous capsule of the kidney by strands of connective tissue which traverse the adipose capsule.

Each kidney is, accordingly, supported by these strands in a space bounded laterally and above by the layers of the renal fascia, and open medially and below. Should these strands become atrophied by wasting disease or ruptured by the pressure of the pregnant uterus, by the improper use of corsets, or by any other cause, the phenomenon of movable or wandering kidney may be set up by slight external violence, the organ tending to shift its place as far as the attachment of its vessels to the main trunks and the arrangement of the renal fascia will permit.

Position and relations.—The kidney is said to lie in the lumbar region. It is, however, intersected by the horizontal and vertical planes which separate the hypochondriac, lumbar, epigastric and umbilical regions from each other, and hence belongs to all these segments of the abdominal space (see fig. 965). Its vertical extent may be said to correspond to the last thoracic and upper two or three lumbar vertebræ, the right lying in most cases from 8 to 12 mm. (⅓ to ½ in.) lower than the left; but exceptions to this rule are not infrequent.

FIG. 1017.—SECTION OF KIDNEY SHOWING THE SINUS. (After Henle.)

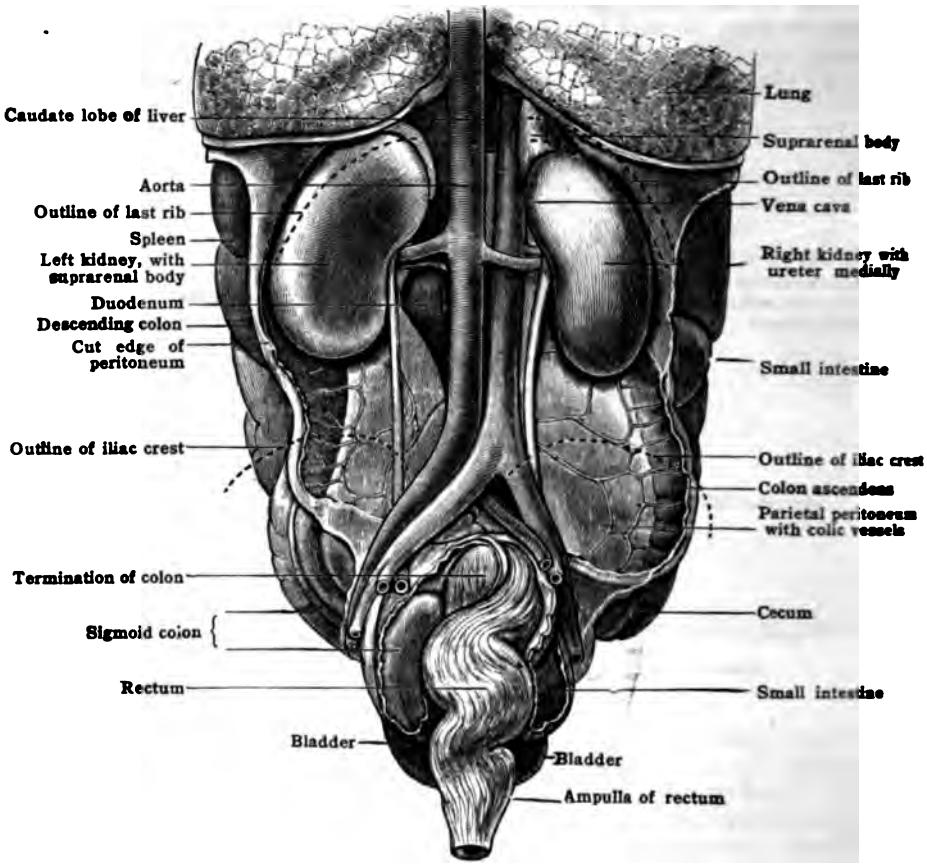


The **posterior surface** (figs. 1018, 1019), rests against the posterior abdominal wall extending upward in front of the eleventh and twelfth ribs, and medialward to overlap the tips of the transverse processes of the first and second lumbar vertebræ; the left kidney usually reaches as high as the upper border of the eleventh rib, the right only to its lower border. The parietal relations of the posterior surface (fig. 1019) on both sides are as follows: (1) the diaphragm; the left kidney, on account of its higher position, entering more extensively into this relation than the right; (2) the 'transversalis area,' corresponding to the portion of the transversalis fascia covering the ventral surface of the quadratus lumborum and adjacent part of the transversus abdominis muscle; (3) the lateral aspect of the psoas; and (4) the last thoracic, iliohypogastric and ilioinguinal nerves and the anterior divisions of the subcostal and first lumbar vessels, all of which run obliquely downward and laterally in front of the quadratus lumborum.

The **upper extremity** of each kidney is crowned by the suprarenal gland (figs. 1018, 1021), which encroaches also upon its ventral surface and medial border and is fixed to it by fibers derived from the subperitoneal tissue.

The anterior surface (fig. 1020) of each kidney was originally completely covered by peritoneum that separated it from neighboring viscera, but, owing to secondary changes whereby the ascending and descending colons, the duodenum and the pancreas become retroperitoneal organs, these come into direct relation with one or the other of the kidneys and separate portions of them from actual contact with the peritoneum. Thus, in the case of the right kidney (figs. 965, 1021), the portion of the anterior surface immediately adjacent to the medial border has the descending portion of the duodenum in direct contact with it, and throughout a zone extending downward and laterally from the middle of the

FIG. 1018.—THE ABDOMINAL VISCERA, SEEN FROM BEHIND.
(From the model of His.)
The kidneys are somewhat lower than usual in their relations to the ribs.



duodenal area to the lateral border, the ascending colon and right colic flexure. Almost the entire upper half, however, and a small portion of the lower pole are covered directly by peritoneum, the upper peritoneal area having an indirect relation with the lower surface of the liver, upon which it produces the renal impression.

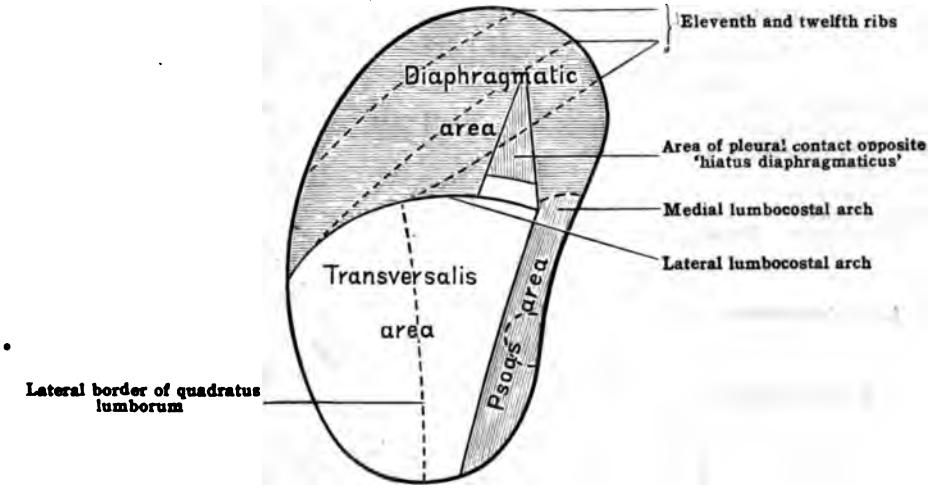
Similarly the anterior surface of the left kidney (figs. 1020, 1021) is in direct contact with the pancreas throughout a broad transverse band situated a little above the middle of the organ, and the splenic artery pursues its tortuous course along the upper border of this pancreatic area, while the corresponding vein is interposed between the pancreas and the surface of the kidney. Below the pancreas, the lateral portion of the kidney is in direct contact with the descending colon and the left colic (splenic) flexure, but the remainder of the lower extremity and a small upper area of the kidney is directly covered by peritoneum. The upper peritoneal area has, as an indirect relation, the posterior surface of the stomach medially, and the spleen laterally (figs. 965, 1021).

The **medial border** of the right kidney approaches the vena cava inferior closely, especially above; that of the left is separated from the aorta by an interval of about 2.5 cm.

Variation in position.—The position of the kidneys in the abdominal cavity is subject to considerable variation. Thus while the upper pole of the right kidney may be said to lie usually opposite the lower half of the eleventh thoracic vertebra, it may be placed as high as the lower part of the tenth thoracic or as low as the upper half of the first lumbar. Similarly while the upper pole of the left kidney is as a rule opposite the middle of the eleventh thoracic vertebra it may lie half a vertebra higher or as low as the lower part of the second lumbar vertebra. The lower poles are distant from the crests of the ilia anywhere from 1.0 cm.–3.0 cm., the distance being, as a rule, somewhat less in females than in males. Occasionally the lower pole may extend even below the iliac crest, especially on the right side.

The lateral border of each kidney lies 8.5–10.0 cm. lateral to the spines of the lumbar vertebræ, a distance that brings them lateral to the lateral edge of the sacrospinalis muscle and even beyond the lateral edge of the quadratus lumborum, so that this border of the kidney may be readily approached through the posterior wall of the body. It must be remembered, however, that the upper part of the kidney rests upon the diaphragm, so that in the event of the twelfth rib being very short there may be danger of the incision being carried too far upward, resulting in injury to the diaphragm and pleura. It is also worthy of note that the diaphragmatic area of the kidney corresponds to the region where a hiatus diaphragmaticus between the costal and lumbar portions of the muscle may occur, and if this be pronounced the upper part of the posterior surface of the kidney may come into more or less direct relations to the pleura (fig. 1019).

FIG. 1019.—DIAGRAM OF RELATIONS OF POSTERIOR SURFACE OF LEFT KIDNEY.



Just as there may be variation in the position of the kidneys, so too there may be considerable variation in the extent to which they are in relation to the various structures mentioned above. And this is especially true as regards their relations to the colons; for if the kidneys were lower than usual they might lie entirely beneath the line of attachment of the transverse mesocolon and thus have no direct relations with either colon, or on the other hand either the ascending or descending colon, or both, may be provided with a mesentery, whereby they would be removed from direct contact with the kidney.

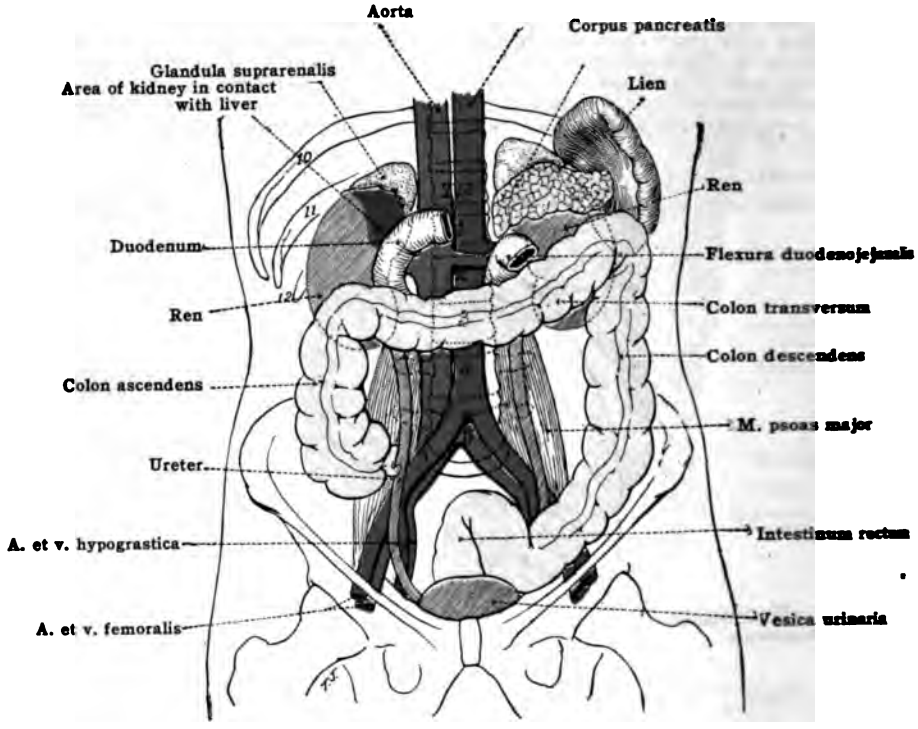
Structure.—A section through the kidney shows its substance to be composed of an external **cortex** [substantia corticalis] and an internal **medulla** [substantia medullaris] (fig. 1022). The medulla consists of a variable number (eight to eighteen) of conical segments termed **renal pyramids** [pyramides renales (Malpighii)], the apices of which project into the bottom of the sinus (fig. 1017) and are received into the primary segments (calyces) of the pelvis, while their bases are turned toward the surface, but are separated from it and from each other by the cortex. The pyramids are smooth and somewhat glistening in section and are marked with delicate striæ which converge from the base to the apex and indicate the course of the renal tubules. The blunted apex, or **papilla**, of each pyramid, either singly or blended with one or even two of its fellows, is embraced by a *calyx* (fig. 1017), and, if examined with a hand-lens, will be seen to present a variable number (twelve to eighty) of minute apertures, the **foramina papillaria**, which represent the terminations of as many ducts (of Bellini) through which the urine passes into the renal pelvis.

The **cortex** may be regarded as composed of two portions, (1) a peripheral layer, the cortex proper, which is about 12 mm. in thickness and extends from the fibrous tunic to the bases of the pyramids, and (2) processes termed **renal columns** [columnæ renales (Bertini)] which dip inward between the pyramids to reach the bottom of the sinus (fig. 1022). In section the cortex is somewhat granular in aspect, and when examined closely shows a differentiation into a number of imperfectly separated portions termed *cortical lobules* [lobuli corticales].

Each of these is composed of a *convoluted portion* [pars convoluta], surrounding an axial *radiate portion* [pars radiata (processus Ferreini)]. The latter consists of a group of tubules which extend from the cortex into the base of one of the medullary pyramids, whence it is also termed a medullary ray; and each medullary pyramid is formed from the rays of a number of cortical lobules, these structures, therefore, greatly exceeding the pyramids in number.

Renal tubules (fig. 1023).—The structure described above is the result of the arrangement of the renal tubules, which constitute the essential units of the kidney. Each of these commences in a spherical **glomerular capsule,** one wall is invaginated by a small *glomerulus* of blood-vessels, the combination of glomerulus and capsule forming what is termed a renal **(Malpighian) corpuscle.** These corpuscles are situated in the convoluted parts of the cortical lobules, and from each of them there arises by a narrow neck a tubule, which quickly becomes wide and convoluted, this portion being termed the **first convoluted tubule.** This enters the radiate part of the cortical lobules, where it narrows again and descends as a straight

Fig. 1020.—Topographic Relations of the Kidneys, etc. Anterior View.



tubule, the **descending limb of Henle's loop,** into the subjacent medullary pyramid, and, turning upon itself, forming the **loop of Henle,** ascends to the cortex as the **ascending limb of Henle's loop,** where it again becomes wide and contorted, forming the **second convoluted tubule.** This returns to the convoluted portion of the cortical lobule, and, becoming narrower, opens with other similar tubules into a straight or collecting **tubule,** which passes into the radiate part of the cortical lobule, then descends into the subjacent medullary pyramid where it unites with other collecting tubules, and finally opens into the renal plevis at the summit of a papilla.

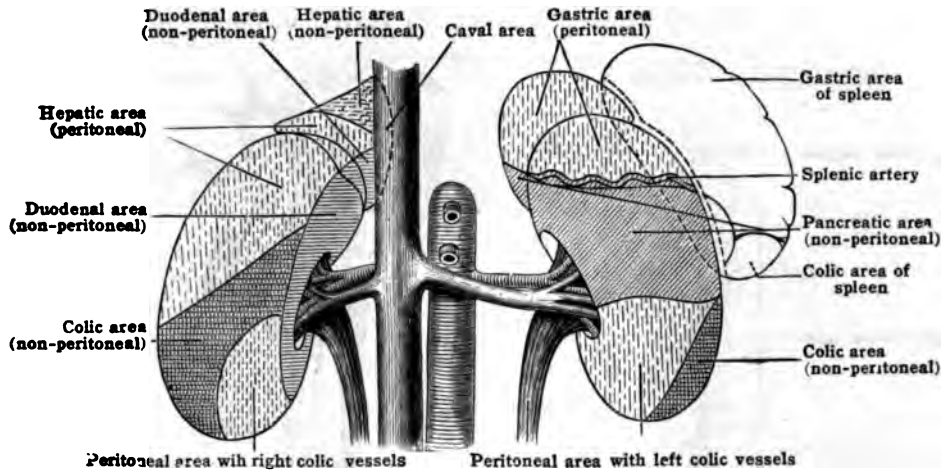
The tubules are lined with epithelium throughout, the cells being flat in the capsule, irregularly cubical and imbricated in the convoluted tubules, flattened in the descending limb of Henle's loop, changing to cuboidal in the loop. The epithelium is cubical in the ascending limb of Henle's loop and in the smaller collecting tubules but becomes columnar in the larger collecting tubules and ducts of Bellini.

Vessels (fig. 1023).—The kidney is very vascular. The larger *arterial branches,* arranged in the sinus as has already been described, enter the substance of the kidney and pass up as the *interlobar arteries* in the renal columns. On reaching the bases of the pyramids they bend so as to run horizontally between these and the cortex, forming the *arcuate arteries* [arteriæ arciformes] from which interlobular branches pass up into the cortex and supply *afferent* branches to the glomeruli. *Efferent* stems which issue from the glomeruli break up into capillaries which supply the tubules contained in the cortex. From the arcuate arteries numerous branches, the *arteriolæ rectæ,* pass down into the pyramids, supplying the tubules of which these are composed. *Veins* corresponding to the arteriolæ rectæ and to the interlobular, arcuate and interlobar arteries drain into the renal veins. At the surface of the kidney, arranged in star-like groups, are the *stellate veins* [venæ stellatæ], which open into the interlobular veins and also communicate with the veins of the adipose capsule. The renal *lymphatics* may be divided into two sets, capsular and parenchymatous. They terminate in the upper lumbar nodes.

Nerves.—The nerves form a plexus accompanying the vessels, and are derived from the sympathetic and vagus through the renal plexuses.

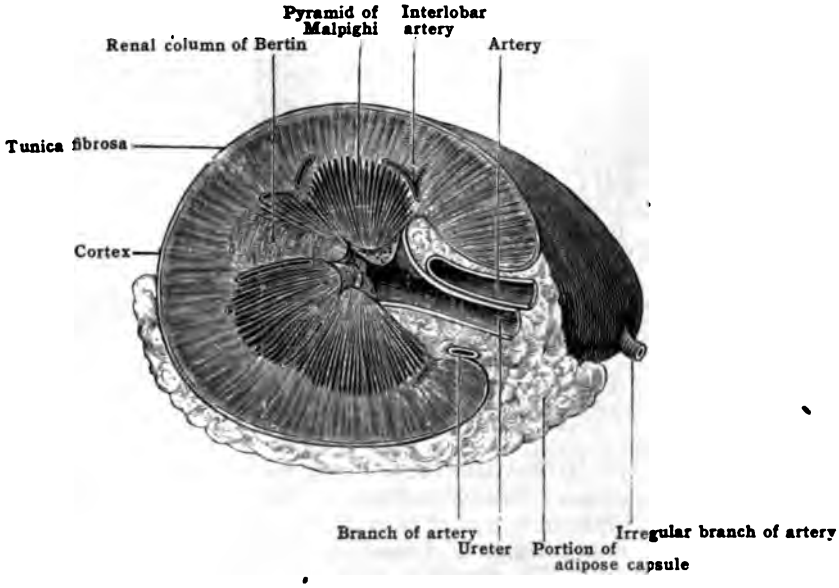
Variations.—The kidney of a fetus differs from that of the adult in being divided into a number of distinct renal lobes, each of which corresponds to the base of a renal pyramid and is capped by a thin layer of cortex. Such a condition is permanent in some of the lower animals; but in man the superficial indications of morphological segmentation usually become obliterated during the progress of growth of the cortical tissue, and are seldom visible after the age of ten.

FIG. 1021.—DIAGRAM SHOWING ANTERIOR RELATIONS OF KIDNEYS AND SUPRARENAL BODIES



Development.—In the development of the embryo, representatives of three different sets of excretory organs occur, the permanent kidney (metanephros) being the last to form. The two earlier sets (pronephros and mesonephros) have a common duct, the **Wolffian duct,** and from the lower end of this an outgrowth develops, which extends upward on the posterior abdominal wall and comes into connection with a mass of embryonic tissue known as the **metanephric blastema.** The outgrowth gives rise to the ureter, pelvis and collecting tubules, while the remaining portions of the tubules are formed from the blastema. For further details, see DEVELOPMENTAL ANATOMY, p. 50.

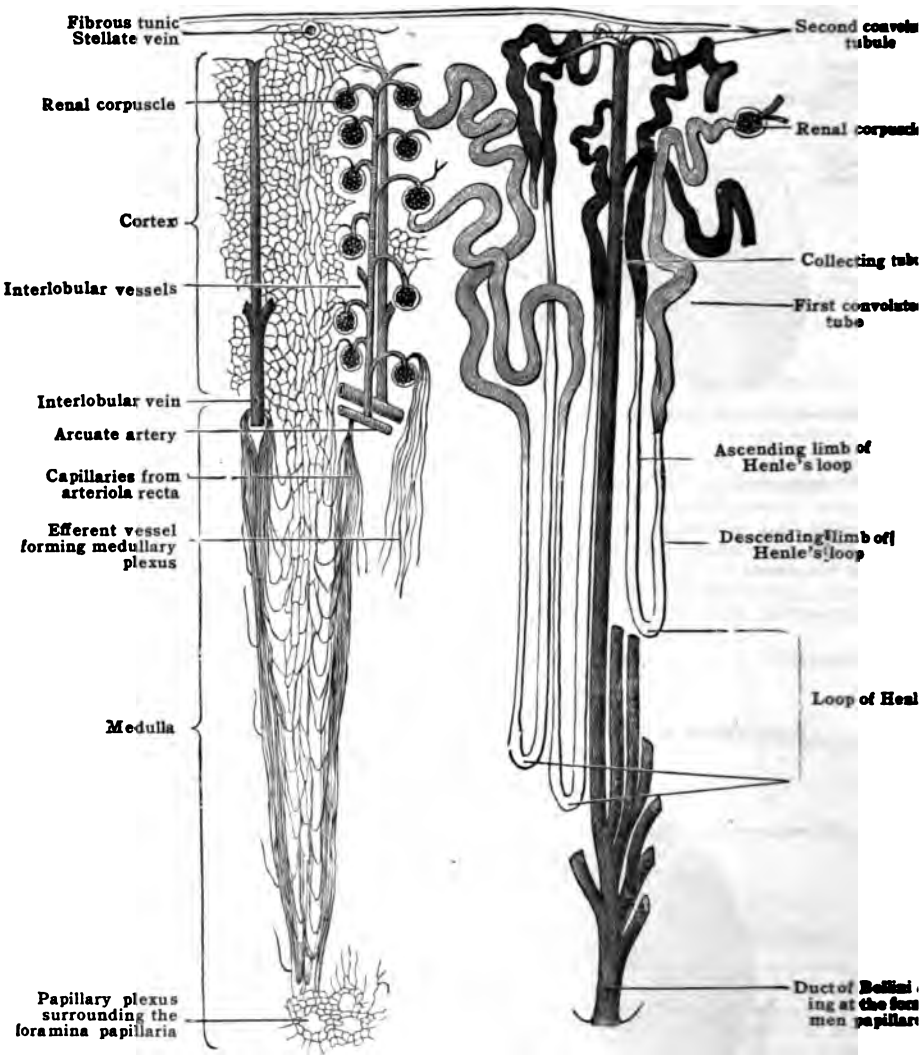
FIG. 1022.—HORIZONTAL SECTION OF KIDNEY.



Various *abnormalities* may result from modifications of the development of the kidneys. (1) Occasionally the ureteric outgrowth of one side fails to develop, the result being the occurrence of a single kidney. (2) The blastema may fail to attain its normal position, in which case the kidney may be situated in the iliac region or even in the pelvis; or the blastema may be drawn into an unusual position, the kidney resting on the vertebral column, or even on the opposite side of the abdomen; (3) or the two blastemas may fuse to a greater or less extent,

forming a 'horse-shoe kidney,' extending across the vertebral column; or, if the fusion be extensive, an apparently single kidney, which may rest upon the vertebral column, or to side of it. Such fused kidneys may be distinguished from single kidneys by the fact that possess two ureters opening normally into the bladder. (4) In rare cases, a blastema ma come divided, an accessory kidney of varying size being thus produced. (5) Finally, in o more of the tubules there may be a failure of the union of the portion derived from the tema with the collecting tubule derived from the ureteric upgrowth, and the secretion h no means of escape from such malformed tubules, they become greatly dilated, produc cystic kidney.

FIG. 1023.—SCHEME OF TUBULES AND VESSELS OF THE KIDNEY.



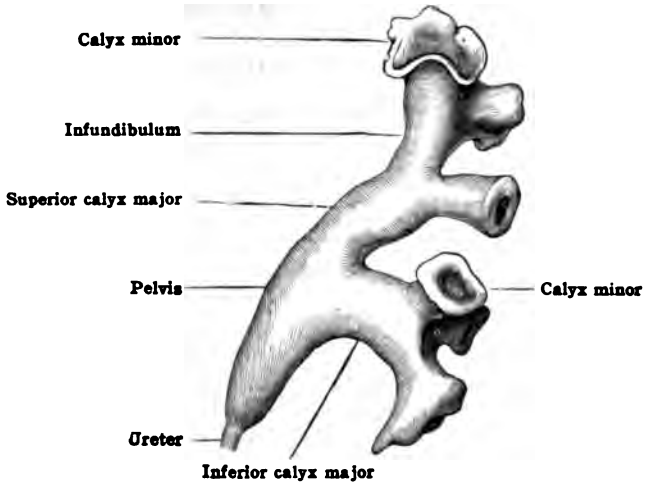
THE URETERS

The **ureter** (figs. 1015, 1018, 1021, 1024, 1026), which conveys the urine f the kidney to the bladder is a tube, expanded and irregularly branched above, narrow and of fairly uniform dimensions throughout the rest of its course. A origin in the renal sinus it consists of a number of short tubes, usually eigh nine, called **calyces minores** (fig. 1024), each of which embraces a renal pap or occasionally two papillæ may be connected with a single calyx. These cal minores open directly or by means of short intermediate tubes (**infundibula**) two short passages, the superior and inferior **calyces majores**, which in turn u after a longer or shorter course to form the **pelvis**. Occasionally a third or mi calyx major is present.

The **pelvis** [pelvis renalis] (fig. 1024) is usually more or less funnel-shaped, being wider above, where it lies between the two lips of the hilus, and narrower below, where it arches downward and medially to become continuous with the ureter proper. It is, however, very variable in shape and in some cases is hardly larger than the ureter. Usually it is flattened dorsoventrally so that its anterior and posterior walls are in contact and its cavity represented merely by a fissure. The majority of the branches of the renal vein and artery lie in front of it, imbedded in fat tissue, and anterior to these are the descending portion of the duodenum on the right side and (usually) the pancreas on the left. The intrarenal portions of the ducts, including the pelvis, are considered parts of the kidney.

The **ureter** proper (fig. 1018) extends from the termination of the pelvis to the bladder, its course lying in the subperitoneal tissue. It is a tube about 5 mm. in diameter when distended and it is fairly uniform in size, except that a slight constriction occurs where it enters the pelvis and a second one occurs at about the middle of its abdominal portion. Its length is variously stated, but the average in the male adult may be taken as about 30 cm., the right being usually a little the shorter.

FIG. 1024.—PELVIS AND UPPER PORTION OF URETER. (After Henle.)



Course and relations.—The course of each ureter may be conveniently divided into two portions, abdominal and pelvic. The **abdominal portion** [pars abdominalis] runs downward and slightly medially and is in relation *posteriorly* with the psoas muscle and its fascia; it crosses the genitofemoral nerve obliquely and in the lower part of its course passes in front of the common iliac artery near its bifurcation. *Anteriorly* it is covered by peritoneum and is crossed by the spermatic or ovarian vessels. *Medially* it is in relation on the right side with the inferior vena cava and on the left with the aorta, the vein being almost in contact with the right ureter, while the artery is separated from the left one by an interval that diminishes from 2.5 cm. above, to 1.5 cm. opposite the bifurcation of the vessel.

The **pelvic portion** [pars pelvina] passes in front of the sacroiliac articulation and then forward and downward upon the obturator internus and its fascia behind and below the psoas, crossing the obturator vessels and nerve and having anterior to it in the female the posterior border of the ovary. It thus reaches the level of the floor of the peritoneal cavity, whereupon, at about the level of the ischial spine, its course is directed forward and medially toward the bladder. In this part of its course *in the male*, it is crossed superiorly and medially by the ductus deferens, and then passes under cover of the free extremity of the vesicula seminalis. *In the female* the ureter runs parallel with, and 8 to 12 mm. distant from, the cervix uteri, passes behind the uterine artery, through the uterine plexus of veins (fig. 531), and beneath the root of the broad ligament, and finally crosses the upper third of the lateral wall of the vagina to reach the vesicovaginal interspace and enters the substance of the bladder at about the junction of its posterior, superior and lateral surfaces.

When the ureters reach the bladder they are about 5 cm. apart. As they pass over into the wall of the bladder they become imbedded in its musculature in which they extend obliquely for a distance of some 2 cm. where they open by slit-like apertures. The lips of these apertures are said to function as valves when the bladder is distended and thus prevent a backward flow of urine. When the bladder is distended the openings of the ureters are about 5 cm. apart, but when contracted the openings are not more than 2.5 cm. apart.

Structure.—The wall of the ureter is about 1 mm. in thickness, and consists of a mucous membrane, a muscular coat, and an external connective tissue investment. The mucous membrane is longitudinally plicated, and is lined by transitional epithelium, continuous with that of the papillæ above and with that of the bladder below. Mucous follicles of simple form have been found in the upper part of the tube. The muscularis is about 0.5 mm. in thickness, and consists of two layers, an external, composed of annular fibers, and an internal, of fibers longitudinally disposed. After the tube has entered the bladder the circular fibers form a kind of sphincter around its vesical orifice; while the longitudinal fibers are continued onward through the wall of the bladder and terminate beneath its mucous membrane.

Vessels and nerves.—The *arteries* supplying the pelvis and upper part of the ureter come from the renal; the rest of the abdominal portion of the ureter is supplied by the spermatic (or ovarian), and its pelvic portion receives branches from the middle hemorrhoidal and inferior vesical; the *veins* terminate in the corresponding trunks; and the *lymphatics* pass to the lumbar and hypogastric nodes. The *nerves* are supplied by the spermatic, renal, and hypogastric plexuses.

Variations.—Occasionally the depression which separates the two calyces majores extends through the pelvis, so that the calyces appear to open directly into the ureter. The fission may also affect the ureter to a greater or less extent, in extreme cases producing a duplication of the tube throughout its entire length with double openings into the bladder.

THE URINARY BLADDER

The **urinary bladder** [vesica urinaria] is a receptacle, whose form, size, and position vary with the amount of its contents. The adult organ in its empty or moderately filled condition lies entirely below the level of the oblique plane of the pelvic inlet; but when considerably distended it rises into the abdomen and shows itself as a characteristic mesial projection above the symphysis, a projection which in extreme distention of the bladder may extend nearly to the level of the umbilicus.

Form.—When distended the bladder assumes in the male an ovoid shape with its longest diameter directed from above downward and backward; but in the female the transverse diameter is the greatest, in accordance with the greater breadth of the pelvic cavity. When empty, it becomes tetrahedral in form. In the child it is somewhat pear-shaped, the stalk being represented by the urachus.

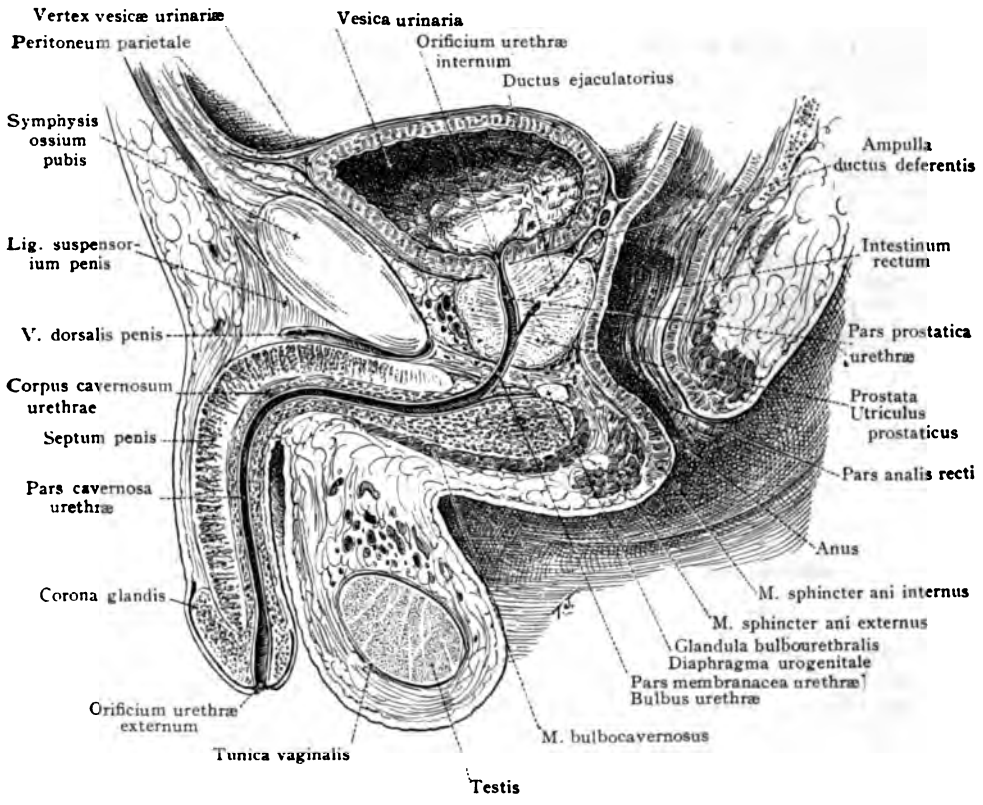
Parts.—For convenience in description four surfaces may be recognized, which are fairly well marked in the empty bladder, but are indistinctly separated when it is distended. The **superior surface** is covered with peritoneum. The two **inferolateral surfaces** rest upon the pelvic diaphragm, and join anteriorly in a rounded border (sometimes termed the anterior surface). The **posterior surface,** sometimes flat and sometimes, especially in old age, convex, forms what is known as the base or **fundus** [fundus vesicæ]. The portion of the bladder between the vertex and fundus is termed the **body** [corpus vesicæ]. The superior and inferolateral surfaces meet at the **vertex** of the bladder, from which the **middle umbilical ligament** (**urachus**) extends to the umbilicus. Inferiorly, in the angle formed by the fundus and the inferolateral surfaces is the **internal urethral orifice** [orificium urethræ internum], by which the bladder communicates with the urethra. The portion of the organ immediately surrounding this is sometimes spoken of as the **neck.**

When the bladder is empty and relaxed, the superior surface sinks down upon the other surfaces, thus becoming concave, and the cavity of the organ is reduced to a T- or Y-shaped fissure. In the contracted empty bladder, especially in the female, the cavity in midsagittal section often more nearly resembles a figure 7 (see fig. 1046).

Relations.—The *anterior border* looks downward and forward toward the symphysis pubis (figs. 1025, 1046). It is uncovered by peritoneum, but is separated from the pubic bones by a space known as the **retropubic or prevesical space** (**cavum Retzii**), which contains a variable quantity of loose fat continuous with the pelvic and abdominal subperitoneal tissue. The *inferolateral surface* on each side is separated from the levator ani and obturator internus by subperitoneal tissue, which usually bears much fat in its meshes and ensheaths the vesical vessels and nerves. Near the border separating the inferolateral from

the superior surface on each side is the obliterated hypogastric artery anteriorly, and (in the male) the ductus deferens posteriorly. The latter passes between the ureter and the wall of the bladder, a little above the level at which the former enters the wall of the bladder, at the angle formed by the superior, inferolateral and posterior surfaces. The *posterior surface* is in direct contact *in the male* (fig. 1025) with the anterior wall of the rectum and with the lower part of the ductus deferentes and the vesiculæ seminales. Between the diverging ductus deferentes there is a triangular space (fig. 1030), whose base is formed by the line of reflection of the rectovesical peritoneal excavation and the apex by the meeting of the ejaculatory ducts at the summit of the prostate. It represents the area of direct contact of the posterior wall of the bladder with the rectum. *In the*

FIG. 1025.—MIDSAGITTAL SECTION OF THE MALE PELVIS. (After Sobotta and Spalteholz.)



female the posterior surface is adherent to the cervix of the uterus and the upper part of the anterior wall of the vagina (fig. 1046), and is usually not in contact with peritoneum. The *superior surface* is entirely covered by peritoneum. It looks almost directly upward into the abdominal cavity and has resting upon it coils of the small intestine and sometimes a portion of the sigmoid colon.

Variation in position.—In the normal condition the bladder of the adult lies below the upper border of the symphysis pubis, but if fully distended it may rise above this level, carrying with it the reflection of peritoneum from its upper surface to the anterior abdominal wall. The anterior surface of the bladder is thus brought into relation with the anterior abdominal wall, being separated from it only by the enlarged prevesical space, and it is thus possible to enter the bladder above the symphysis pubis without penetrating the peritoneum.

In the infant, owing to the smaller extent of the pelvic cavity, the bladder lies at a somewhat higher level than in the adult and rises into the abdominal cavity. Indeed the entire bladder is above the horizontal level of the pubic crests, the urethral orifice being behind the upper margin of the symphysis pubis. As the child learns to walk, however, this position gradually alters and usually by the age of six years the adult relations have been acquired.

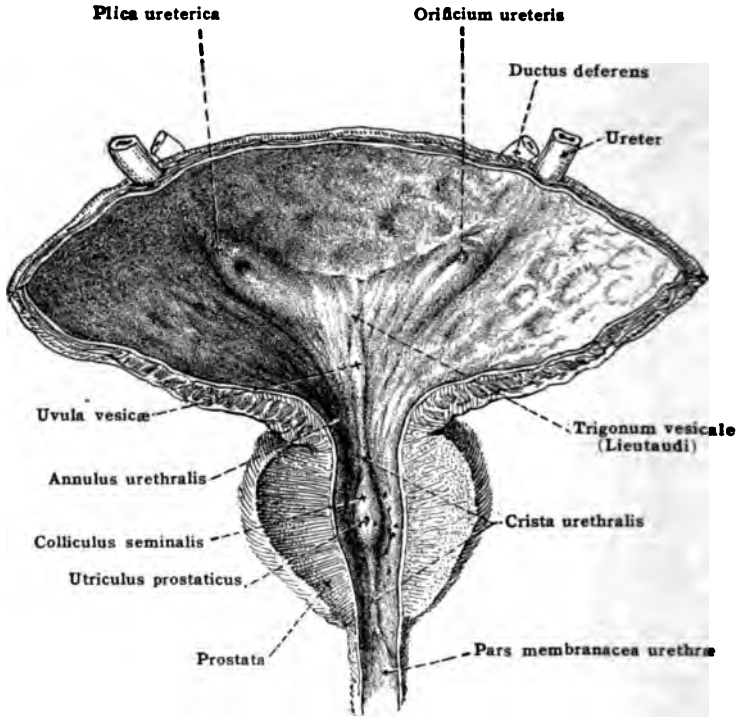
The fixation of the bladder.—The reflections of the peritoneum from the superior surface of the bladder to the anterior abdominal wall and the corresponding walls of the pelvis are sometimes described as the superior, lateral and posterior *false ligaments*. Furthermore there extends from the apex of the bladder to the umbilicus a fibrous cord, the *urachus*, the remains

of the embryonic allantois; this is described as the ***middle umbilical ligament*** of the bladder (fig. 1046). The *lateral umbilical ligaments* are formed by the obliterated hypogastric arteries which carry the fetal blood to the placenta and in the adult are represented by fibrous cords passing along the sides of the bladder and ascending to the umbilicus.

In addition to these structures certain thickenings of the endopelvic fascia, where it comes into relation with the bladder and prostate gland, constitute what are termed the true ligaments. Two such thickenings extend from the anterior surface of the capsule of the prostate gland, or from the lower part of the anterior aspect of the bladder in the female, to the pubic bones and constitute what are known as the *middle puboprostatic (pubovesical) ligaments*, with which muscle fibers [m. pubovesicalis] are usually associated. Similarly, thickenings of the fascia extending from the sides of the prostate gland or from the sides of the lower part of the bladder to the lateral walls of the pelvis form the *lateral true ligaments*.

Muscle fibers [m. rectovesicalis] also occur in the subperitoneal tissue contained within the peritoneal folds (posterior false ligaments) extending from the back of the bladder to the posterior wall of the pelvis and bounding the rectovesical pouch of peritoneum in the male. They correspond to the *mm. rectouterini* of the female.

FIG. 1026.—THE TRIGONE OF THE BLADDER AND THE FLOOR OF THE PROSTATIC URETHRA.



The internal surface.—The mucous membrane lining the internal surface of the bladder is soft and rose-colored during life, and in the empty bladder is thrown into irregular folds which become effaced by distention. It is modified over a triangular area at the base of the bladder, termed the ***trigone*** [trigonum vesicæ (Lieutaudi)] (fig. 1026) whose three angles correspond with the orifices of the urethra and of the two ureters. This area is paler in color and free from the plication that characterizes the rest of the mucous membrane; it is bounded posteriorly by a transverse ridge, the *plica ureterica*, extending between the orifices of the ureters, and toward the urethral orifice presents a median longitudinal elevation, the *uvula vesicæ*, which is apt to be especially prominent in aged persons. The *internal urethral orifice* is normally situated at the lowest point of the bladder, at the junction of the inferolateral and posterior surfaces. It is surrounded by a more or less distinct circular elevation, the ***urethral annulus***, and is usually on a level with about the center of the symphysis pubis and from 2.0 to 2.5 cm. behind it.

Structure.—The general characteristics of the *mucous membrane* of the bladder, which is lined by epithelium of the transitional variety, have already been described. It rests upon a loose *submucous coat* which is made up of areolar tissue. The greater part of the thickness of the wall is formed, however, of the *muscular coat*, consisting of smooth muscle-tissue, the fibers of which are arranged in three more or less distinct layers. The *outer layer* is composed

mainly of longitudinal fibers, some of which are continued forward to the pubis from the neck of the bladder to form the mm. pubovesicales and others backward to form the mm. rectovesicales. To this outer layer the term *m. detrusor urinæ* has been applied, but it should be noted that it does not contract independently of the circular layer. The *middle layer* is thicker than the outer and more uniformly developed. It consists of fibers having for the most part a circular direction and is well developed over all the upper portion of the bladder, but becomes thinner in the region corresponding to the trigone. It is here that the *inner layer* is chiefly developed, consisting of fibers, which are situated partly in the submucous tissue and have a general longitudinal direction throughout the region of the trigone. At the neck of the bladder, however, they form a strong circular bundle, which is continued into the prostatic portion of the urethra and forms what is termed the *internal sphincter* of the bladder.

Vessels.—The *arteries* of the bladder are usually three in number, the superior, middle and inferior vesical, branches of the hypogastric artery; the fundus also receives branches from the middle hemorrhoidal and in the female twigs are also sent to it from the uterine and vaginal arteries. The *veins* form an extensive plexus at the sides of the bladder, from which stems pass to the hypogastric trunk. The *lymphatics* accompany the veins and communicate with the hypogastric nodes, some of those from the fundus passing to nodes situated at the promontory of the sacrum.

Nerves.—The *nerves* are derived partly from the hypogastric sympathetic plexus and partly from the second and third sacral nerves. The fibers from the latter constitute the nervi erigentes, stimulation of which produces contraction of the general musculature and relaxation of the internal sphincter. On each side of the bladder there is formed a sympathetic *vesical plexus*, from which *superior* and *inferior vesical* nerves pass to the corresponding parts of the bladder.

Development.—In the earlier stages of development (cf. p. 51) the urogenital ducts and the digestive tract open below into a common cavity, the *cloaca*, from the ventral portion of which a long tubular outgrowth, the *allantois*, extends out to the placenta through the umbilical cord. Later the cloaca becomes divided in the frontal plane into a ventral portion which receives the urogenital ducts, and a dorsal portion, which becomes the lower end of the rectum. From the upper part of the ventral portion the bladder is developed. Since the cloaca is lined by endoderm the epithelial lining of the bladder is mainly derived from that embryonic layer, but it is worthy of note that portions of the lower ends of the ureters are taken up into the wall of the bladder, giving rise to the area of the trigone, whose lining membrane is thus of mesodermal origin. The portion of the allantois within the body of the fetus is transformed after birth into a fibrous cord, the *urachus*.

The **urethra** will be considered later in connection with the reproductive organs.

B. THE REPRODUCTIVE ORGANS

The reproductive organs include those of the male [organa genitalia virilia and those of the female [organa genitalia muliebria].

THE MALE REPRODUCTIVE ORGANS

The reproductive organs of the male consist of (1) two **testes** in which the spermatozoa are formed, (2) their ducts, the **ductus deferentes,** enclosed throughout a portion of their course in the **spermatic cord;** and the **seminal vesicles,** reservoirs for the semen, connected with the ductus deferentes; (3) the **penis,** the organ of copulation, which is traversed by the urethra; (4) the **urethra,** a canal into which the ductus deferentes open and which also gives exit to the contents of the bladder; (5) the **prostate gland,** a musculoglandular structure surrounding the beginning of the urethra; (6) the **bulbourethral glands** which open into the urethra.

1. The Testes and Their Appendages

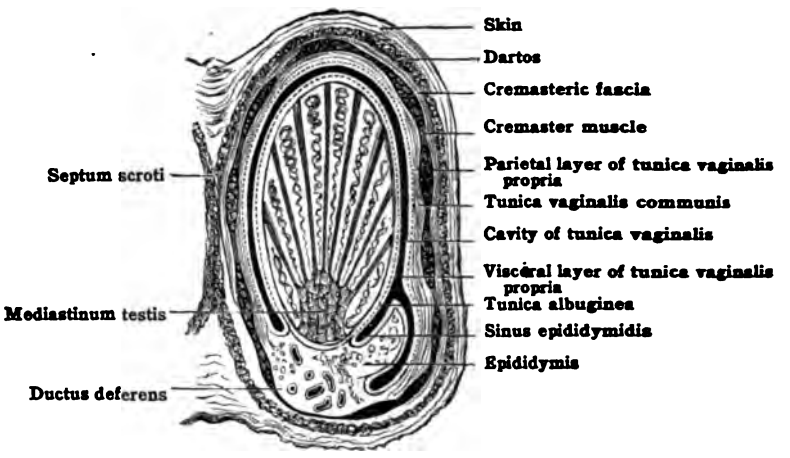
The scrotum.—The two testes, together with the beginning of the ductus deferentes, are contained within a pouch, the *scrotum*, which is divided into two compartments by a median sagittal septum, the edge of which is indicated on the surface by a ridge-like thickening of the integument, termed the *raphe*.

This double condition of the scrotum is explained by its origin from the fusion of two outpouchings of the lower portion of the abdominal wall, the inguinal canals forming, as it were, the necks of the outpouchings. The testes are primarily retroperitoneal abdominal organs, but later they descend through the inguinal canals into the scrotal outpouchings, where they lie between the peritoneal sac which each of these contains and the remaining layers of the wall, thus retaining their retroperitoneal position. The peritoneal sacs are at first in communication with the abdominal cavity, but after the descent of the testes each undergoes degeneration in its upper part, the cavity disappearing and the peritoneal tissue becoming converted into a portion of the connective tissue in which the ductus deferens and the vessels and nerves associated with it are imbedded in their course through the *spermatic cord*. The portion of the sac

in relation with each testis persists, however, and wrapping itself around that structure forms for it a serous investment, the *tunica vaginalis propria* (fig. 1027).

The *integument* of the scrotum is more or less pigmented and presents numerous transverse ridges extending laterally on either side from the raphe. It is furnished in the adult with coarse, scattered hairs and its sebaceous and sudoriparous glands are well developed. The deeper layers of the dermis, have a pinkish color, and form what is termed the *dartos* (fig. 1027), the coloration being due to the presence in it of numerous smooth muscle fibers, which are for the most part arranged at right angles to the wrinkles of the surface and are the cause of these. The more superficial fibers of the dartos, like the rest of the integument, form a common investment for both testes, but the deeper ones of either side bend inward at the raphe and assist in the formation of the septum.

FIG. 1027.—HORIZONTAL SECTION OF THE SCROTUM AND TESTIS. (Diagrammatic.)



Internal to the dartos and closely related to it is a layer of laminated connective tissue, the *external spermatic fascia*. It is destitute of fat and is continuous at the subcutaneous inguinal ring with the intercrural fibers. It is succeeded by the *cremasteric fascia*, which contain longitudinal bands of striated muscle-tissue, forming what is termed the *cremaster muscle* (figs. 420, 1027) and is continuous above with the fibers of the internal oblique muscle of the abdomen. Internal to this is a thin layer of connective tissue, the *tunica vaginalis communis*, or infundibuliform fascia which is continuous with the transversalis fascia through the inguinal canal.

Forming the innermost layer of the scrotum is the *tunica vaginalis propria*, which forms the serous investment of the testis and, as has been stated, is of peritoneal origin. Like other similar serous investments it has the form of a double sac, the outer or parietal layer of which is closely adherent to the tunica vaginalis communis and contains numerous plain muscle-fibers. The inner or visceral layer is thinner and closely invests the testis and a portion of the epididymis, being reflected from the inferior and posterior parts of the latter to be continuous with the parietal layer. Toward the upper part of the lateral surface of the testis it is folded in between that structure and the epididymis, forming a well-marked pocket the *sinus epididymidis* (digital fossa) (figs. 1027, 1028), whose upper and lower lips form what are termed the *ligamenta epididymidis*.

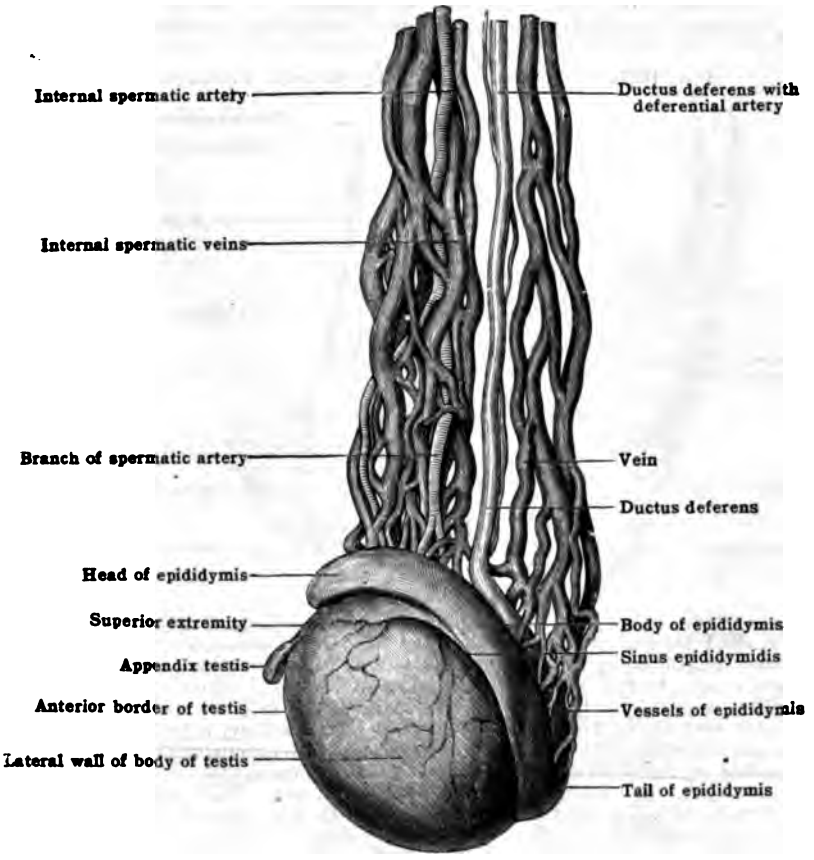
Vessels and nerves.—The skin and dartos of the scrotum are supplied partly by the perineal branch of the internal pudendal *artery* and partly by the external pudendal branches of the femoral. The deeper layers are supplied by the spermatic branch of the inferior epigastric. The *veins* accompany the arteries, the external pudendals opening into the internal saphenous vein near its termination. The *lymphatics* terminate in the more medial inguinal nodes. Several *nerves* take part in the supply of the scrotum. The external spermatic branch of the genitofemoral gives sensory branches to the anterior and lateral surfaces and also supplies the external cremaster muscle; the posterior surface is supplied by the perineal branch of the pudendal nerve; and the inferior surface by the perineal branches of the posterior femoral cutaneous. The anterior surface of the scrotum is also supplied by anterior scrotal branches of the ilioinguinal. The smooth musculature is probably supplied by the internal spermatic nerve from the hypogastric plexus.

Hernia.—The communication of the tunica vaginalis propria with the abdominal peritoneum is usually obliterated within a few days after birth, but sometimes the process of obliteration is more or less incomplete. If the communication remains open there is a free passage

for a loop of the intestine to enter the cavity of the tunica vaginalis, such a condition constituting what is known as the *congenital* variety of inguinal hernia. If the communication be interrupted only at the upper part of the original sac, so that the cavity of the tunica vaginalis propria extends a considerable distance up the spermatic cord a hernia, passing through the inguinal canal, may invaginate the upper part of the tunica vaginalis into the lower, producing what is termed the *encysted* variety of hernia. Or if, finally, the obliteration of the communication begins in the neighborhood of the testis, a funnel-shaped prolongation of the peritoneal cavity may extend downward into the spermatic cord, and hernia into this constitutes the variety known as *hernia into the funicular process.* (Cf. also p. 1398.)

The testis and epididymis.—The **testes** (fig. 1028) are the essential male organs of reproduction and are contained within the scrotum. They are two in number, each being of a flattened oval form, with two *surfaces*, *medial* and *lateral*,

FIG. 1028.—THE LEFT TESTIS WITH VESSELS AND DUCT. (After Sappey.)



two *borders*, *anterior* and *posterior*, and two *extremities*, *superior* and *inferior*. To the whole of the posterior border there is attached the *epididymis*, formed by the efferent ducts. The testis is obliquely placed, so that the medial surface also looks somewhat forward and downward. The average dimensions of the testis are: 4–5 cm. in length and 2.5–3 cm. in width.

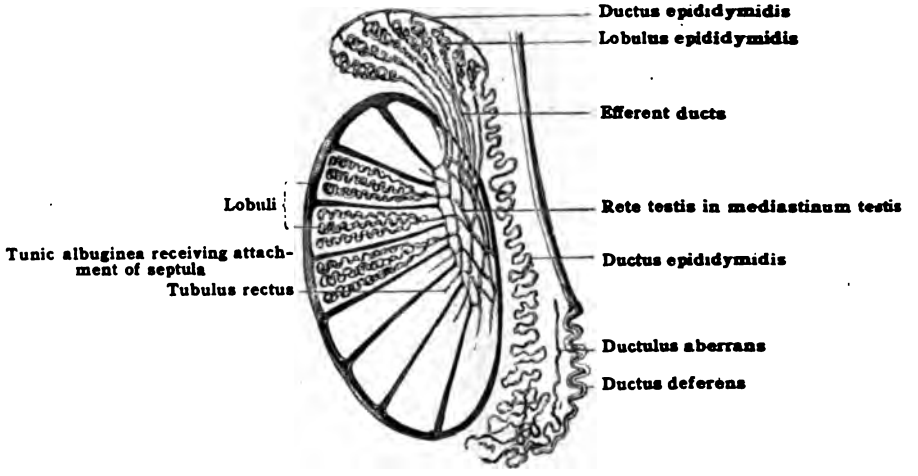
The surface of the testis is covered by the visceral layer of the tunica vaginalis propria except where it is in contact with the epididymis. Within the visceral layer of the tunica vaginalis is a dense white inelastic capsule, the *tunica albuginea*, beneath which is a looser and more vascular layer which extends along the septula and thus gives rise to a vascular investment of the lobules. From the inner surface of the albuginea, lamella of connective tissue, known as *septula*, converge toward the posterior border of the testis and toward its upper part unite to form a network (fig. 1029), the *mediastinum testis* (or corpus Highmori), through which blood-vessels and lymphatics enter and leave the testis. The tubules of the testis as they pass into the meshes of the mediastinum form the *rete testis*.

The septula divide the substance of the testis into a number of compartments or *lobuli*, each of which is occupied by a number of slender, greatly contorted canals, the *seminiferous tubules* [tubuli seminiferi], from whose epithelial lining the spermatozoa are formed. The tubules of each lobule converge to form a single, almost straight duct and these *tubuli recti* extend toward the mediastinum, where they pass into the rete testis. In the lobules the seminiferous tubules are imbedded in a loose connective tissue that contains certain peculiar cells, the *interstitial cells*, to which has been attributed the formation of an internal secretion.

The **epididymis** (fig. 1028), which lies along the posterior border of the testis, is an elongated structure with a *body* [corpus epididymidis], enlarged above to form the *head* [caput] and to a less extent below to form the *tail* [cauda]. It is invested by a tunica albuginea, continuous with, but much thinner than that of the testis, and is formed mainly by the greatly contorted duct of the epididymis, which is continued into the ductus deferens.

The head is formed by 12–14 tubules, the *efferent ducts* (fig. 1029), which take their origin from the rete testis as almost straight tubules, but gradually become greatly coiled, so that each duct has the form of an elongated cone, its coiled portion forming what is termed a *lobulus*

FIG. 1029.—DIAGRAM OF THE TESTICULAR TUBULES.



epididymidis. At their coiled ends the various efferent ducts open into a single tube, the *ductus epididymidis*. Its diameter is only about 0.4 mm., but it measures 6.0–7.0 meters (18–21 feet) in its entire length, being coiled so extensively as to be contained within the body and tail of the epididymis. In this latter region it passes over into the ductus deferens.

Vessels.—The principal *artery* supplying the testis is the internal spermatic, from which branches are also sent to the epididymis. The deferential artery, a branch of the superior vesical, also sends branches to the epididymis and enters into extensive anastomoses with the testicular branches of the internal spermatic, and anastomoses also occur with the vessels supplying the scrotum. The *veins* correspond to the arteries. The *lymphatics* of the testis and epididymis unite to form four to six large stems which pass upward in the spermatic cord to terminate in the lower lumbar nodes.

Morphology.—For the development of the testis, see DEVELOPMENTAL ANATOMY, p. 52. The testis is primarily an abdominal organ and is developed in close relationship with the provisional kidney [mesonephros] whose duct, indeed, becomes the ductus deferens and some of whose tubules, becoming the efferent ducts, place the seminiferous tubules in communication with the ductus deferens. The epididymis may therefore be said to be developed from the mesonephros. The portions of this structure that are not concerned in the formation of the efferent ducts disappear for the most part; a few of the tubules persist, however, as rudimentary organs associated with the epididymis. Among these may be mentioned one or more blindly ending, coiled tubules, varying from 5–30 cm. in length, which are connected with the ductus epididymidis usually in the tail of the epididymis. They are known as the *ductuli aberrantes* (fig. 1029) and may be regarded as persistent mesonephric tubules. Another of the rudimentary organs is the *paradidymis* (*organ of Giraldès*), which is a whitish body, situated immediately above the head of the epididymis, and is composed of irregularly coiled tubules, which terminate blindly at both extremities. They may be regarded as efferent ducts that have failed to connect with the testis and are of interest in that they sometimes develop into cysts connected with the epididymis.

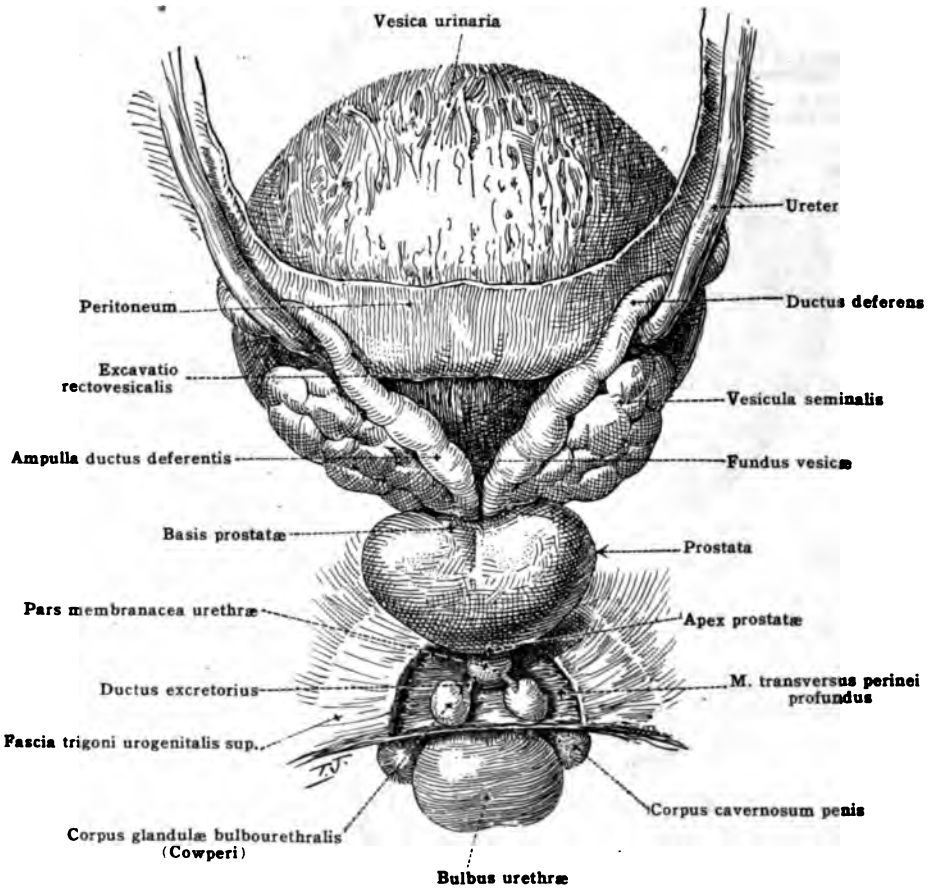
In addition there is frequently attached to the upper extremity of the testis a solid, oval body composed of connective tissue, known as the *appendix testis* (*hydatid of Morgagni*) (fig. 1028). It measures from 3 to 8 mm. in length and its significance is doubtful. A similar, though smaller structure, the *appendix epididymidis*, is attached less frequently to the head of the epididymis. It is usually provided with a distinct stalk and contains a cavity; it is believed to

represent the upper end of the Müllerian duct, present in the embryo and giving rise to the tuba uterina in the female, but almost completely degenerating in the male (fig. 1051).

The testis begins its descent from the abdominal cavity into the scrotum at the third month of fetal life and reaches the abdominal inguinal ring at about the sixth month, but it is not until shortly before birth that it arrives at its final location in the scrotum. The cause of the descent is still uncertain, but it is supposed to be partly due to the failure of a band of connective tissue, which extends from the lower pole of the embryonic testis to the bottom of the scrotal pouch, to keep pace with the growth of the body walls. This ligament, which is known as the *gubernaculum testis*, thus becomes relatively shorter and draws the testis downward toward the point of its attachments to the scrotum. There are various features in the descent, however, that cannot be explained by the simple traction of the gubernaculum and it must be regarded as a complicated growth process whose meaning is yet uncertain. The gubernaculum testis apparently undergoes degeneration after the testis has reached its definitive location and cannot be recognized in connection with the adult testis.

Occasionally the descent of the testis is interrupted, the organ remaining either in the abdomen or in the inguinal canal. This condition of **cryptorchism** is always associated with a suppression of the function of the organ.

FIG. 1030.—RELATIONS OF BLADDER, DUCTUS DEFERENS, SEMINAL VESICLES, PROSTATE, ETC. Posterior view.



2. THE DUCTUS DEFERENTES AND VESICULÆ SEMINALES

Each **ductus (vas) deferens** is the continuation of a ductus epididymidis and extends from the tail of the epididymis to the prostatic portion of the urethra. At its beginning it ascends along the posterior border of the epididymis (*testicular portion*) and is at first slender and tortuous (fig. 1029), but before reaching the level of the head of the epididymis it becomes straighter and thicker (fig. 1028), owing to the development in its walls of strong layers of longitudinal and circular smooth muscle-tissue. Thence it is continued almost vertically upward as one of the constituents of the spermatic cord (*funicular portion*) to the subcutaneous inguinal ring, and, entering this, traverses the inguinal canal (*inguinla*

portion), still forming a portion of the cord. At the abdominal ring it separa from the other constituents of the cord and, looping over the inferior epigast

FIG. 1031.—DUCTUS DEFERENTES AND VESICULÆ SEMINALES. (After Sappey.)

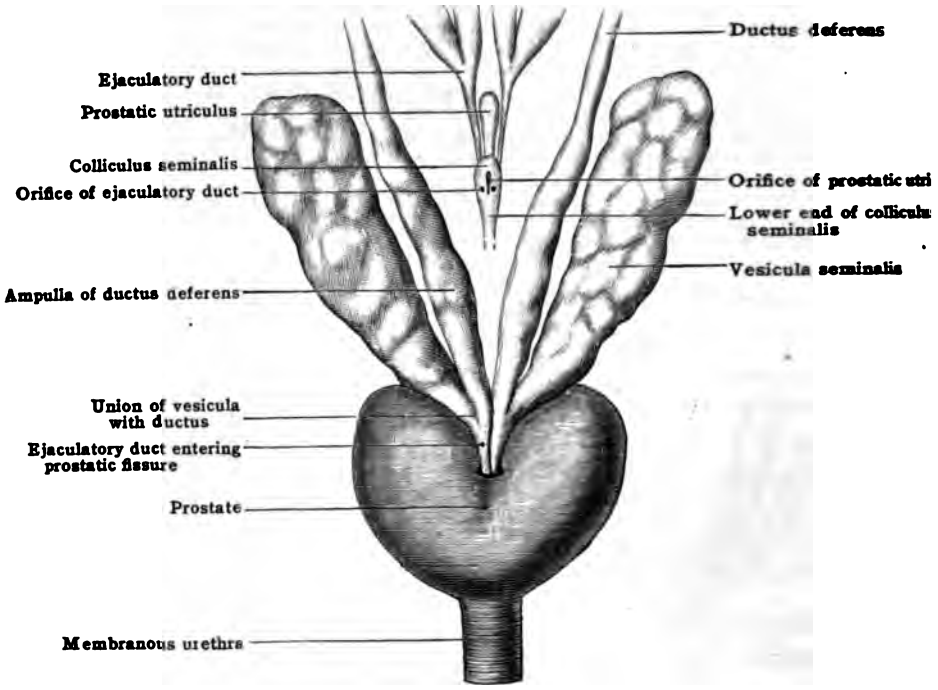


FIG. 1032.—DUCTUS DEFERENS AND VESICULA SEMINALIS DISSECTED. (After Sappe

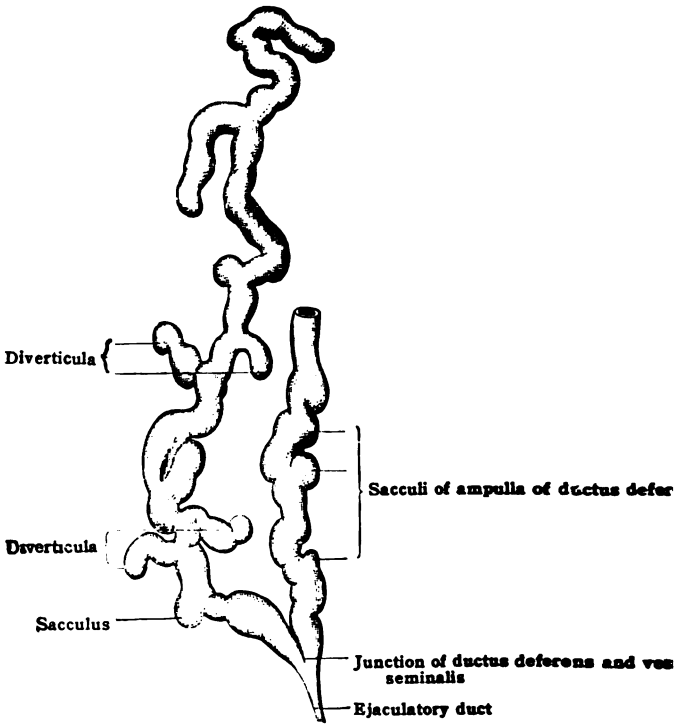
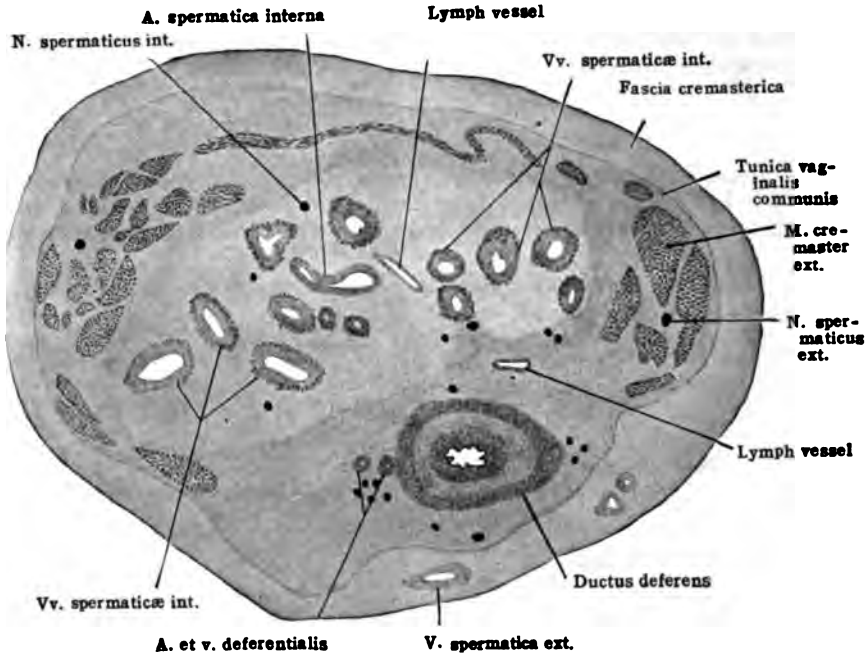


artery near its origin, passes downward and backward over the lateral surfac the bladder (*pelvic portion*). At the junction of the posterior and superior s

faces of the bladder it passes medially to the ureter and is then continued downward, forward and medially upon the base of the bladder until it reaches the prostate gland (figs. 1030, 1031). Just before it reaches the prostate gland each ductus deferens presents an irregular spindle-shaped enlargement, the *ampulla* (figs. 1030 –1032), whose walls are somewhat sacculated. Just beyond this it is joined upon its lateral surface by the excretory duct of a club-shaped lobulated structure, the **vesicula seminalis.** The union of the ductus deferens with the excretory duct of the seminal vesicle gives rise to the *ductus ejaculatorius* which traverses the substance of the prostate and opens into the urethra on the colliculus seminalis (fig. 1031). Each vesicle measures 4.5–5.5 cm. in length and has a greatest diameter of about 2 cm. It rests upon the posterior surface of the bladder, lying parallel with and lateral to the corresponding ductus deferens, and in its upper one-third is in relation posteriorly with the peritoneum which forms the anterior wall of the rectovesical pouch, while below it is in contact with the an-

FIG. 1033.—CROSS-SECTION OF THE SPERMATIC CORD.



terior wall of the lower part of the rectum, through which it may be palpated. Indeed, the two vesiculæ, together with the ductus deferentes, form the lateral boundaries of the triangular area at the base of the bladder, through which that organ is in relation to the rectum.

Each vesicle is enclosed within a fine capsule of connective tissue, which contains numerous smooth muscle-fibers and is continuous below with the capsule of the prostate gland. On removing this capsule the vesicle will be found to consist of a greatly coiled tube, 10–12 cm. in length, which ends blindly and has attached to it on either side a number of short diverticula (fig. 1032). The walls of the tube and diverticula are formed of smooth muscle-tissue, arranged in layers similar to those of the ductus deferentes, and are lined by a much folded mucous membrane. The epithelium of this membrane is composed of two layers of cells, an inner columnar and an outer cuboidal. These cells and the adjacent connective tissue contain considerable quantities of a yellowish-brown pigment. The cells of the epithelium exhibit appearances which lead to the supposition that they contribute a secretion to the seminal fluid. In addition to having this function the vesiculæ may serve as receptacles for the spermatozoa. They arise as diverticula from the embryonic ductus deferens, and it is worthy of note that a number (4 or 5) of similar but quite small diverticula arise from the upper part of each ductus ejaculatorius.

Vessels and nerves.—The *artery* supplying the ductus deferens is the a. deferentialis, a branch of the superior vesical. It accompanies the ductus to the tail of the epididymis and also gives a branch to the vesicula seminalis. The latter also receives branches from the middle hæmorrhoidal and inferior vesical arteries. The deferential *vein* accompanies the ductus deferens to the base of the bladder where it breaks up into a plexus that communicates with

the seminal venous plexus formed by the veins from the seminal vesicles. This joins with the vesical and pudendal plexus and so communicates with the hypogastric vein. The *lymphatics* of the ductus deferentes and seminal vesicles pass to the external iliac and hypogastric nodes. The *nerves* of both structures are derived from the hypogastric plexus.

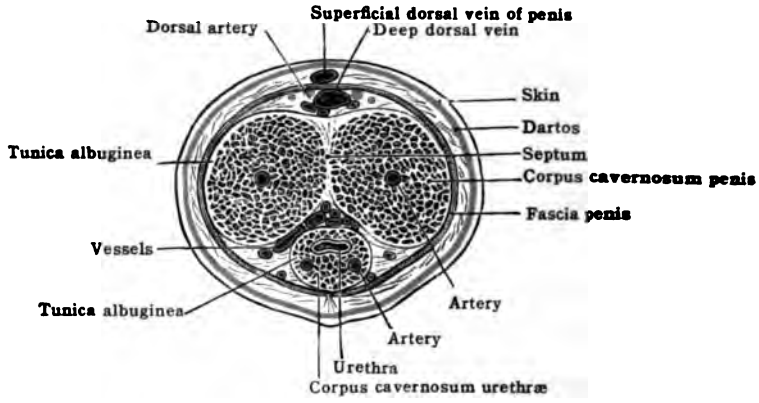
The spermatic cord.—In its descent through the inguinal canal into the scrotum the testis necessarily carries with it the ductus deferens and the testicular vessels and nerves, these structures coming together at the abdominal inguinal ring to form what is termed the *spermatic cord* [funiculus spermaticus]. This structure extends, therefore, from the abdominal inguinal ring, through the inguinal canal and the neck of the scrotal sack to the testis, and is enclosed within the same investing layers as the testis.

The various essential constituents of the spermatic cord are as follows (figs. 1028, 1033): (1) the *ductus deferens*, occupying the posterior surface of the cord and having associated with it the deferential artery and veins and the deferential plexus of nerve-fibers; (2) the *internal spermatic artery*, which occupies the axis of the cord and is surrounded by (3) the *internal spermatic veins* which form a complicated network, known as the *pampiniform plexus;* (4) the *testicular lymphatics;* and (5) the *internal spermatic plexus* of nerves from the hypogastric plexus and (6) branches of the *external spermatic vessels and nerve* for the supply of the cremaster muscle. All these structures are united by a loose connective tissue.

3. The Penis

The **penis** is formed by three rod-like bodies composed of erectile tissue (figs. 1034, 1035), firmly united together and invested by fascia and integument. When this erectile tissue becomes engorged with blood the organ assumes an

Fig. 1034.—Transverse Section through the Body of the Penis.



erect position, but otherwise it is pendulous, hanging downward in front of the scrotum from its attachment to the symphysis pubis. The erectile bodies are, however, prolonged backward beyond the symphysis pubis into the perineal region, and it is customary to speak of this perineal portion as the *root* of the penis [radix penis] or *pars fixa* in contrast to the *body* of the penis [corpus penis] or *pars libera*.

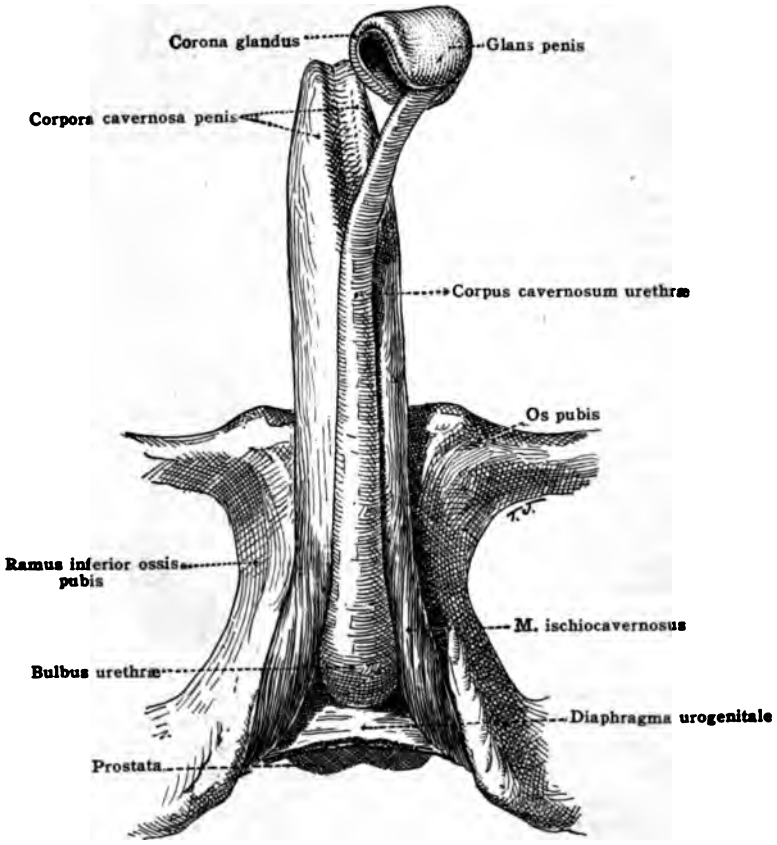
The **body of the penis** in its flaccid condition is almost cylindrical, but in erection it becomes somewhat triangular in section, what was the anterior surface or *dorsum penis** becoming flattened, while the opposite one, the *urethral surface* [facies urethralis], becomes more rounded. At the free extremity of the penis there is a blunt conical enlargement, the glans penis (fig. 1035), at the apex of which is the external orifice of the urethra. The glans is separated from the body by a constriction, the *neck* [collum glandis], and from this region a fold of integument arises, which more or less completely encloses the glans, forming the *prepuce* [præputium] (fig. 1036). The prepuce is quite free from the glans dorsally but in the ventral mid-line it is attached, almost to the urethral orifice.

* It should be noted that the terms 'dorsum' and 'dorsal' are used for the penis in a sense directly opposite their usual meaning.

by a narrow line of adhesion, the *frenulum* [frenulum præputii], which contains blood-vessels of considerable size. The base of the glans has a well-marked rounded border, the *corona* [corona glandis], and is deeply concave for the reception of the distal ends of the corpora cavernosa penis.

The integument of the penis is continuous with that of the scrotum and like it is pigmented and contains no fat. Immediately below it there is a layer of non-striated muscular tissue, the *dartos*, and beneath this a layer of loose connective tissue, containing the superficial vessels and nevers of the penis; beneath this again is a denser, elastic sheet of connective tissue, the *fascia penis* (fig. 1034), which encloses the erectile bodies as far as the base of the glans and is continuous with the superficial fascia of the perineum and inguinal region. Where it passes beneath the symphysis pubis it receives from the anterior surface of the latter a strong band of fibrous tissue, which forms the *suspensory ligament* of the penis [lig. suspensorium penis.]

FIG. 1035.—DISSECTION OF THE PERINEUM SHOWING THE STRUCTURE AND RELATIONS OF THE PENIS.



Two of the erectile bodies of the penis, the **corpora cavernosa penis,** are paired (figs. 1034, 1035). They are attached at their proximal ends to the base of the tuberosity of the ischium of each side, and in this part of their extent are termed the *crura penis*, being composed of fibrous connective tissue, which has resting upon it the m. ischiocavernosus (see Section V). The two **crura** are situated in the lateral portions of the superficial perineal interspace and pass forward parallel with the rami of the ischium and pubis, gradually becoming transformed into cavernous erectile tissue. Shortly before they reach the level of the symphysis pubis the two corpora come into contact in the median line, their medial walls fusing to form a *septum*, and thus united they extend throughout the entire length of the body of the penis, occupying the dorsal portion of the space enclosed by the fascia penis (fig. 1034). They terminate at the posterior surface of the glans, where they taper somewhat to be received into its basal concavity (fig. 1036). The septum in its proximal part forms a complete partition between the two bodies, but distally it is broken through by numerous clefts by which the blood lacunæ of the two bodies are placed in communication.

Each corpus cavernosum penis consists of a strong elastic fibrous sheath, the *tunica albuginea*, from which trabecula extend into the substance of the organ, dividing it into a network of communicating cavities, into which open terminal branches of the a. profunda penis, which traverses the axis of the corpus. These cavities consequently are to be regarded as vascular lacunæ, which, becoming engorged with blood, produce the enlargement and erection of the organ.

The third erectile organ is the **corpus cavernosum urethræ** (formerly 'corpus spongiosum') (figs. 1034–1036), so called because it is traversed throughout its entire length by the urethra. It is an unpaired, median structure, having no bony attachments and begins posteriorly in the superficial perineal interspace with an enlargement, the **bulb** [bulbus urethræ] (fig. 1035), whose posterior surface rests on the superficial fascia of the urogenital diaphragm and is enclosed by the m. bulbocavernosus. Anteriorly the bulb gradually tapers to a rather slender cylindrical portion, the *body*, very uniform in diameter, which extends throughout the entire length of the body of the penis, lying in the median line beneath the fused corpora cavernosa penis (figs. 1034, 1035). At the neck of the penis it undergoes a sudden enlargement to form the *glans*, the whole of that structure which has already been described, being formed by the corpus cavernosum urethræ. The structure of the corpus cavernosum urethræ is essentially the same as that of the corpora cavernosa penis, the tunica albuginea, however, being much thinner.

Vessels and nerves.—The principal *arterial* supply of the penis is derived from the internal pudendal artery (see p. 647), although the proximal portion of its integument is also supplied by the external pudendal branches of the femoral artery. The *veins* from the integument collect into one or more stems, the superficial dorsal vein, which runs along the dorsal midline and, bifurcates, draining into the great saphenous vein of each side (fig. 563). The deep veins from the corpora cavernosa open into a median deep dorsal vein, which communicates with the internal pudendal veins and terminates in the pudendal plexus. Both the superficial and deep *lymphatics* terminate in the superficial inguinal nodes. The lymph-vessels from the glans are said to follow those of the urethra and end in the deep inguinal and external iliac nodes.

The *nerves* supplying the penis are the anterior scrotal branches of the ilioinguinal, and the perineal branches and dorsal nerve of the penis from the pudendal. Sympathetic fibers also pass to the penis from the hypogastric plexus and these with fibers from the third and fourth sacral nerves constitute what is termed *nervus erigens*, since stimulation of it produces erection of the organ. An anatomical provision for the production of this phenomenon has been found in the occurrence of peculiar thickenings of the intima of the arteries of the penis, by which the lumina of the vessels are greatly diminished or even occluded when in a state of moderate contraction, as when the organ is flaccid. When the arteries are dilated the intimal thickenings become reduced in height and the blood is afforded a free passage into the lacunar spaces of the corpora cavernosa, which thus become engorged.

4. The Male Urethra

The **urethra** is the canal which extends from the bladder to the extremity of the glans penis and serves for the passage of both the urine and the seminal fluid. In its course (fig. 1036) it traverses first the prostate gland, then the urogenital diaphgram and then the entire length of the corpus cavernosum urethræ, and may thus be regarded as being composed of three portions.

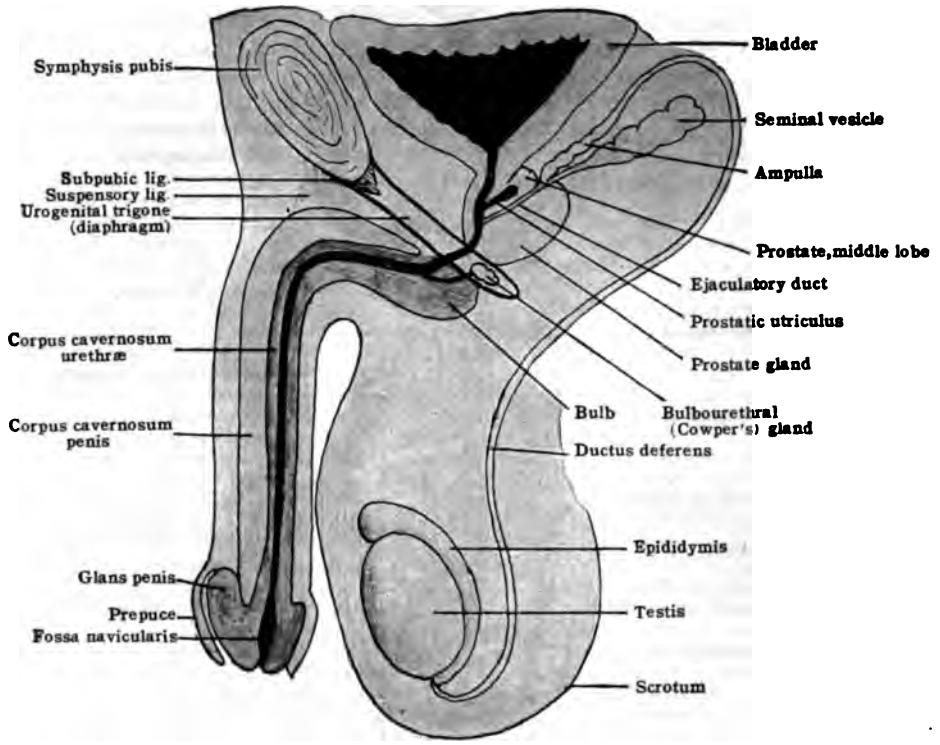
The **prostatic portion** [pars prostatica] (fig. 1036) extends almost vertically downward from the neck of the bladder, traversing the substance of the prostate gland. In its proximal part there is on its posterior wall a median longitudinal ridge, the *crista urethralis*, which below dilates into an oval enlargement, the *colliculus seminalis* (figs. 1026, 1037), to accommodate which there is a marked widening of the lumen of the urethra in this part of its course. At the center of the colliculus there is an elongated opening of a pouch of varying depth, termed the *utriculus prostaticus* ('uterus masculinus'), which corresponds to the lower part of the vagina in the female (see p. 1297). Situated one on either side near the utriculus are the much smaller openings of the *ejaculatory ducts*. Owing to the prominence formed by the colliculus a cross-section of the urethra in this region is somewhat ∩-shaped, and at the bottom of the furrows on either side of the median elevation are the minute openings of the numerous ducts of the prostate gland (fig. 1037).

On its emergence from the prostate gland the urethra at once penetrates the deep layer of fascia of the urogenital diaphragm and enters the deep perineal interspace, this portion of its course being known as the **membranous portion** [pars membranacea]. Its direction is now downward and slightly forward, curving

beneath the subpubic ligament, from which it is separated by a plexus of veins and by the fibers of the *sphincter urethræ membranaceæ*, which form an almost complete investment for it. The lumen of this part of the urethra is much narrower than that of the prostatic portion, and since it traverses the rather unyielding fascia of the urogenital diaphragm it is less dilatable than in other parts of its extent, with the exception of the external orifice.

Passing through the superficial layer of fascia of the urogenital diaphragm the urethra then enters the bulb of the corpus cavernosum urethræ (fig. 1036) and is invested throughout the remainder of its extent by this structure; hence this portion is known as the **cavernous portion** [pars cavernosa]. In its proximal part

FIG. 1036.—MIDSAGITTAL SECTION (DIAGRAMMATIC) SHOWING MALE BLADDER, URETHRA, ETC.

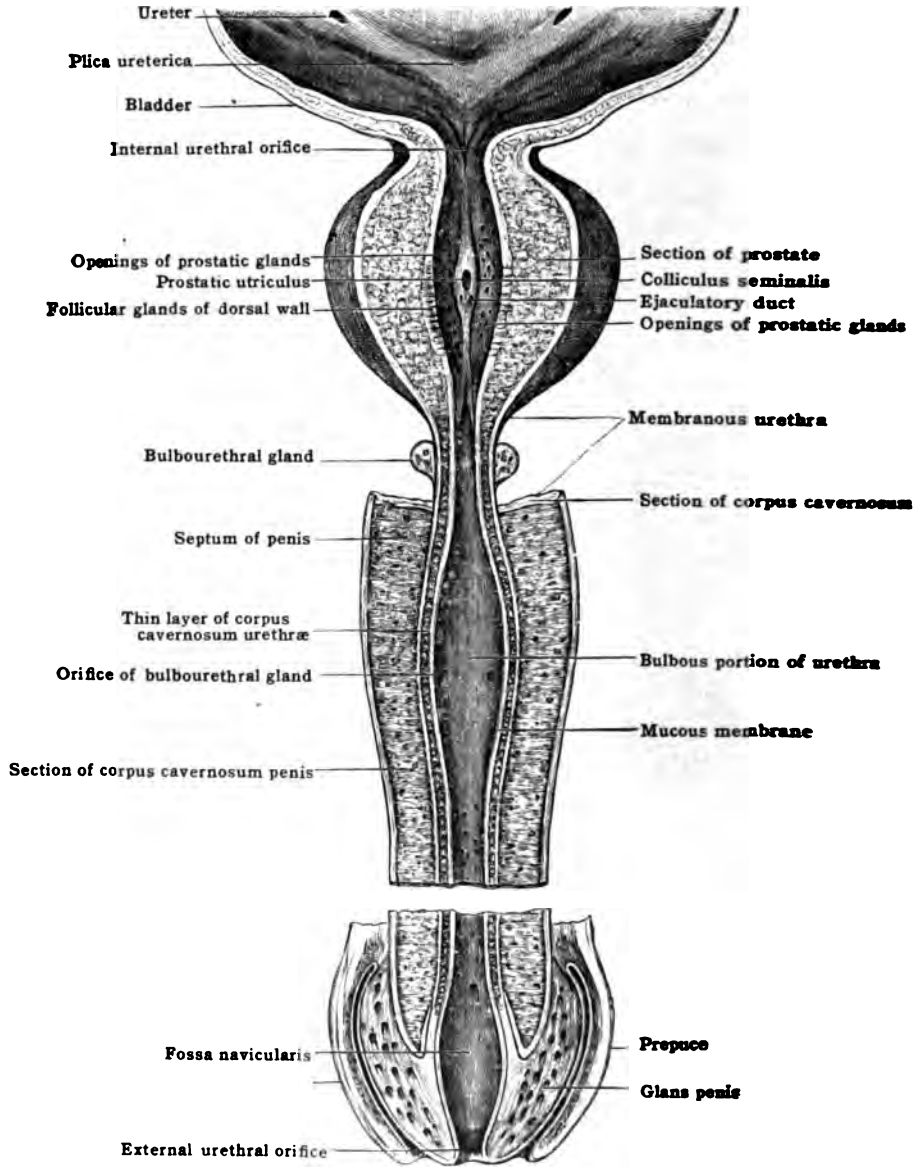


this lies in the superficial interspace of the perineum and passes almost directly forward; but more distally, where it enters the body of the penis, it accommodates itself to the position of that organ, which it traverses lengthwise, lying in the midline near its ventral surface (fig. 1034). Thus the proximal portion of the cavernous and the whole of the membranous and prostatic portions have a fixed position, whence they are sometimes associated as the *pars fixa* of the urethra, while the penial portion forms the *pars mobilis*. On entering the bulb the lumen of the urethra dilates somewhat and in this region has opening into it the ducts of the bulbourethral glands (fig. 1037), but as it enters the body of the corpus cavernosum it diminishes again and maintains a uniform diameter throughout the extent of that structure. When it reaches the glans penis it undergoes another dilation, which is known as the *fossa navicularis* (fig. 1037), beyond which it diminishes to the slit-like *external orifice*, situated at the extremity of the glans and forming the least dilatable portion of the entire urethral canal.

Throughout the greater part of its extent the cavernous portion of the urethra shows upon its dorsal wall the openings of numerous tubular depressions of the mucous membrane, the *urethral lacunæ* [lacunæ urethrales (Morgagnii)]. There is frequently found in the middorsal line of the proximal part of the fossa navicularis, a valve-like fold [valvula fossæ navicularis] of the mucous membrane which gives rise to a pocket sufficiently large to receive the point of a small catheter. Numerous minute glands [gl. urethrales] open upon the surface of the urethral mucosa. They are most abundant in the anterior wall, but occur also on the sides and floor.

Dimensions of the urethra.—The entire length of the urethra is somewhat variabl different individuals, the greatest variation being in the length of the pars mobilis. Of the fixa the prostatic portion is 2.5–3.0 cm. in length, the membranous portion about 1.0 cm., the fixed part of the cavernous portion 6.5 cm., the entire pars fixa having thus a length of what over 10.0 cm. (4 in.). The average diameter of the urethra is 5.0–7.0 mm., but it v noted that the canal presents in its course three dilations; namely, (1) at the fossa n ularis, which begins about 0.5 cm. from the external orifice; (2) the bulb of the corpus ca

FIG. 1037.—THE MALE URETHRA, WITH SURROUNDING PARTS.



sum urethræ; and (3) in the prostatic portion. Furthermore there are two regions in whicl is distinctly narrowed; namely, at the external orifice and in the membranous portion. Wh the remaining portions are capable of considerable distention, these are relatively inelas the maximum diameter to which they may be dilated being about 10 mm. Arranged in ascending order according to their capability for distention the parts would have the followi order: external orifice, membranous portion, penial portion, prostatic portion, bulbar porti

5. THE PROSTATE GLAND

The prostate gland [prostata] (figs. 1025, 1026, 1030, 1036 and 1037) is a mas of glandular and muscular tissue surrounding the proximal portion of the ma

urethra, and may, indeed, be regarded as a special development of the wall of this portion of the canal. It is a more or less flattened conical structure whose *base* [basis prostatæ] is in contact with the lower surface of the bladder and the *apex* [apex prostatæ] with the deep fascia of the urogenital diaphragm. Its *anterior surface* [facies anterior] is behind the symphysis pubis, from which it is separated by the pudendal plexus of veins and a considerable amount of areolar or adipose tissue in the lower part of the prevesical space of Retzius. Its *posterior surface* [facies posterior] is in contact with the anterior wall of the lower portion of the rectum. Laterally it is in relation with the levatores ani. From the neighboring endopelvic fascia it receives a fibrous *sheath*, containing the venous prostatic plexus and loosely connected with the denser fibrous *capsule* of the prostate.

The *urethra* enters the base of the prostate near its anterior border and descends through it almost vertically, so that the greater portion of the gland is posterior to the canal. On the posterior surface of the gland is a more or less distinct median vertical groove, which serves to separate the *lateral lobes* [lobus dexter et sinister], although the demarcation is merely superficial. The groove terminates above in a well-marked notch on the posterior border of the base, and immediately in front of this there is a deep funnel-shaped depression of the surface, which receives the ejaculatory ducts (figs. 1031, 1036).

Beginning at this depression two grooves pass forward and slightly lateralward across the surface of the base of the prostate, marking off a more or less pronounced median elevation, which, when enlarged, constitutes what is termed the *middle lobe* [lobus medius] (fig. 1036); since this lies beneath the trigone of the bladder behind the internal orifice of the urethra its enlargement may produce more or less occlusion of the latter. Ordinarily, however, this middle portion of the prostate, seen in median section between the urethra and the ejaculatory duct, forms merely a commissure [*isthmus prostatæ*] joining the lateral lobes.

Dimensions.—The longest *axis* of the prostate, which is almost vertical in the erect posture measures 2.5–3.0 cm., the *transverse* diameter at the base is 4.0–4.5 cm. and the *thickness* 2.0–2.5 cm. Its *weight* is normally 20–25 grms. but in old age it may be double that, its dimensions having correspondingly increased.

Structure.—The prostate consists of some 15–30 branched tubular glands imbedded in a stroma of connective tissue, containing a large amount of smooth muscle-tissue and forming at the surface of the prostate a strong fibromuscular *capsule* from which prolongations are contributed to the pubovesical ligaments and muscles. The glands, which vary greatly in their development, are outgrowths from the mucous membrane of the urethra, into which their ducts open at the bottom of the grooves that lie lateral to the colliculus seminalis; similarly, the matrix with its muscle tissue is evidently the modified muscular coat of the urethra. Consequently there is no distinct demarcation between the wall of the urethra and the substance of the prostate, and from the developmental standpoint the prostate is to be regarded as the modified wall of the urethra.

The fact that the prostate shows a special development at puberty and undergoes more or less extensive degenerative changes with the cessation of the reproductive function, as seen in old age and in castrates, indicates that it is associated physiologically with the reproductive organs. Its secretion is a thin alkaline fluid, which may contain round or elongate, concentrically layered bodies, measuring 0.3–0.5 mm. in diameter and known as *amyloid bodies*, although they are really albuminous in chemical composition. They are constantly found in adults in the lumina of the glands and may become calcified. The secretion has been found to have a stimulating effect upon the spermatozoa, and this may be its principal function.

Vessels and nerves.—The *arterial* supply of the prostate is derived from the inferior vesical and middle hemorrhoidal branches of the hypogastric artery. The *veins* form a rich prostatic plexus in the immediate vicinity of the gland, this being part of the pudendal plexus around the lower part of the bladder and communicating posteriorly with the hemorrhoidal plexus and superiorly with the vesical plexus. It drains finally into the hypogastric vein. The *lymphatics* are very abundant and form a network on the posterior surface of the gland from which several vessels pass to the hypogastric nodes. The *nerves* are derived from the hypogastric plexus.

6. The Bulbourethral Glands

The **bulbourethral glands** [gl. bulbourethralis (Cowperi)] or **Cowper's glands** (figs. 1030, 1036, 1037) are two small tubuloalveolar glands which lie one on either side of the membranous portion of the urethra, imbedded among the fibers of the sphincter urethræ membranaceæ, between the two layers of fascia of the urogenital diaphragm. Each is a rounded body with a diameter of 4.0–9.0 mm. and is drained by a duct [ductus excretorius] which perforates the superficial fascia of the diaphragm and, entering the substance of the bulb of the corpus cavernosum urethræ, traverses it to open on the floor of the bulbar portion of the urethra after a total course of 3.0–4.0 cm. They have a mucoid secretion.

THE FEMALE REPRODUCTIVE ORGANS

The organs of reproduction in the female consist of (1) the *ovaries*, the essential organs of reproduction; (2) the *tubæ uterinæ* (Fallopian tubes), which serve as

FIG. 1038.—THE FEMALE ORGANS OF REPRODUCTION. (Modified from Sappey.) (Vagina divided and laid open behind.)

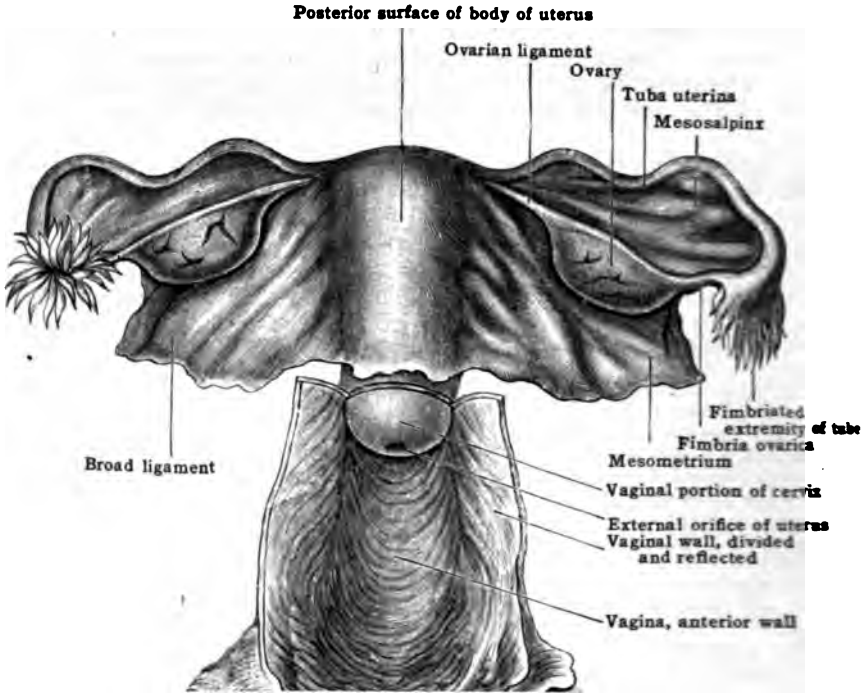


FIG. 1039.—DIAGRAMMATIC SAGITTAL SECTION OF THE BROAD LIGAMENT.

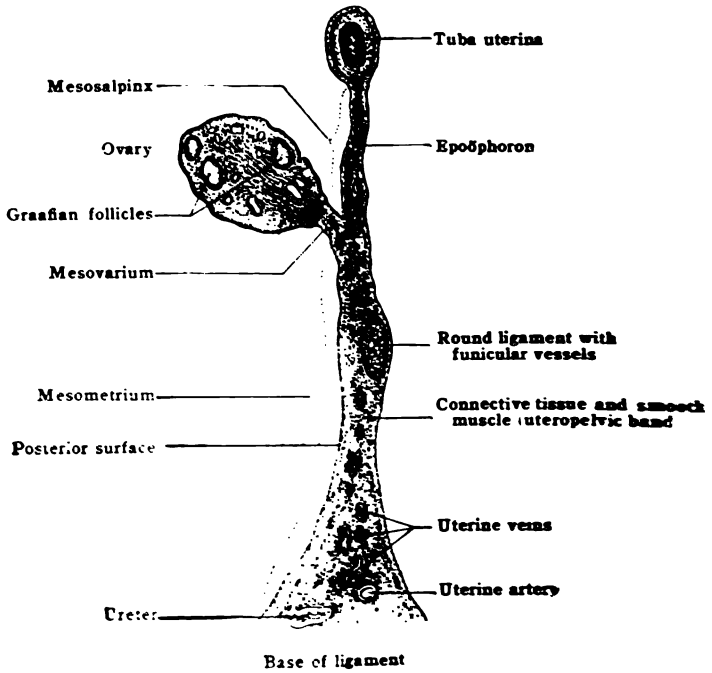
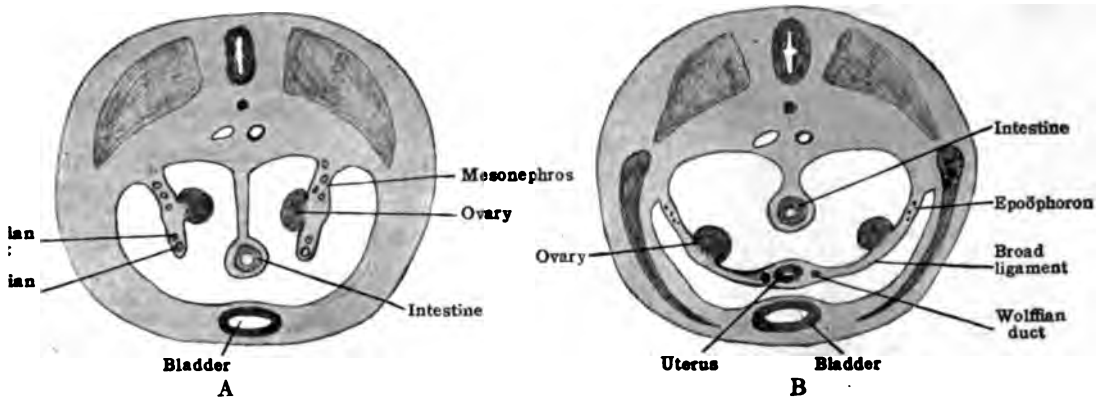


ducts for the conveyance of the ova to 3. the *uterus*, in which the embryo normally undergoes its development; 4. the vagina, a canal by which the ute

is placed in communication with the exterior; and (5) the *external genitalia.* In addition it will be necessary to consider here the female *urethra,* although it differs from that of the male in that it serves merely as a passage for the contents of the bladder and does not transmit the reproductive elements.

Broad ligament.—The ovaries, uterine tubes and uterus are entirely contained within the minor pelvis and are associated with a transverse fold of peritoneum which rises from the floor of the pelvic cavity between the bladder and the rectum, incompletely dividing the cavity into an anterior and a posterior compartment. It is known as the *broad ligament* of the uterus [lig. latum uteri] (figs. 1038, 1039, 1047). The broad ligament appears to extend laterally from the sides of the uterus to the lateral walls and floor of the pelvis, although in reality it extends across the pelvic cavity from side to side and encloses the uterus between the two layers of which it is composed. It is attached to the floor of the pelvis below, where the two layers are reflected, the one upon the anterior wall of the pelvis and the superior surface of the bladder, and the other posteriorly over the floor of the pelvis to the posterior pelvic wall and the rectum, forming the anterior wall of a deep depression between the rectum and uterus, known as the *rectouterine pouch*

FIG. 1040.—CROSS-SECTIONS OF THE BODY ILLUSTRATING THE DEVELOPMENT OF THE FEMALE UROGENITAL SYSTEM. A, AT HIGHER LEVEL. B, AT LOWER LEVEL.



(*of Douglas*) [excavatio rectouterina (cavum Douglasi)] (figs. 1041, 1046). Its lower border is continuous with the lateral borders passing upward upon the sides of the pelvis, resting upon the pelvic fascia. The upper border is free and contains the fundus of the uterus in the midline and the uterine tube on either side. The most lateral portion of the upper border forms the *suspensory ligament of the ovary* (figs. 1041, 1046), through which the ovarian vessels enter the broad ligament.

Attached to the posterior layer of the broad ligament a little below its upper border and therefore projecting into the posterior compartment of the pelvis, there is a horizontal shelf, termed the **mesovarium,** since it has the ovary attached to its free edge (fig. 1039). The portion of the broad ligament above this is known as the **mesosalpinx** (salpinx = tuba), while that below is termed the **mesometrium** (metra = uterus). The remaining structures that occur between the two layers of the broad ligament will be described with the organs with which they are associated, but it is to be noted that the ligament in its upper part is broader than the transverse diameter of the pelvic cavity and its sides are accordingly folded back upon the lateral walls of the cavity, following the course of the uterine tubes.

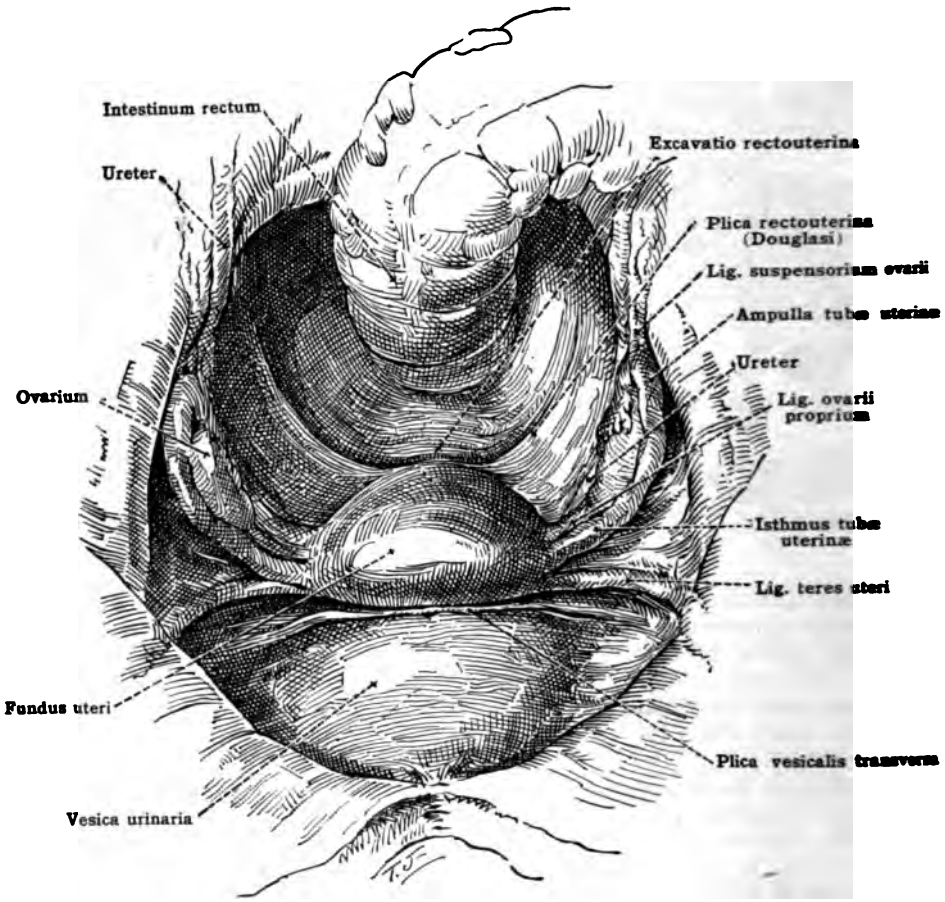
Development.—The broad ligament is the adult representative of the fold of peritoneum which encloses the embryonic excretory organ, the mesonephros. This is for a time a voluminous organ, projecting under cover of the peritoneum from the dorsal wall of the abdomen and bearing upon its medial wall a thickening, the **genital ridge** from which the reproductive gland develops (fig. 1040,A). In the free edge of the peritoneal fold two ducts occur, the **Wolffian duct,** which is the duct of the excretory organ and becomes the ductus deferens of the male, and the **Müllerian duct.** With the progress of development the two Müllerian ducts fuse in the lower portions of their course to form the uterus and vagina (prostatic utriculus of the male), while in their upper parts they remain separate and form the tubæ uterinæ. By this fusion the two peritoneal folds are brought into continuity at their edges, and (the mesonephros de-

generating on the formation of the permanent kidney) constitute the broad ligament (fig. 1040,B). This structure therefore contains between its two layers the uterus and the remains of the mesonephros, and has the ovary attached to its posterior surface. In the male what corresponds to the broad ligament fuses with the peritoneum covering the posterior surface of the bladder.

1. The Ovaries

Form and position.—The *ovaries* [ovaria] (figs. 1038, 1039, 1041, 1046) are two whitish organs, situated one on either side of the pelvic cavity. Each has somewhat the shape of an almond. It is attached by its anterior border [margo mesovaricus] to the border of the mesovarium, and since it is along this line of attachment that the vascular and nerve supply enters the substance of the organ

Fig. 1041.—The Female Pelvic Organs Viewed from Above. (Spaltehols.)



this border is spoken of as the *hilus* [hilus ovarii]. The opposite border is free [margo liber]. The larger rounded end is directed toward the free extremity of the tuba uterina and hence is known as the *tubal extremity* [extremitas tubaria], while the other, the *uterine extremity* [extremitas uterina], is directed toward the uterus; the two surfaces, owing to their topographic relations, are known as the *lateral* and *medial surfaces* [facies medialis et lateralis].

The exact position of the ovary in the pelvis is subject to some variation, but usually it lies almost in a sagittal plane (fig. 1041) against the lateral wall of the pelvis, resting in a distinct depression, the *fossa ovarica*. This fossa is lined by peritoneum and is bounded above by the external iliac vessels and behind by the ureter and uterine artery, while beneath its floor are the obturator vessels and nerve. The long axis of the ovary is almost vertical when the body is erect, the tubal pole being upward; the mesovarial border is directed forward and some-

what laterally, its free border backward and medially, while its surfaces look almost laterally and medially.

Frequently, however, the uterus is displaced to one side, dragging the uterine extremity of the opposite ovary (by the attachment of the ovarian ligament) toward the midplane. The long axis of the ovary thus becomes oblique, approaching more or less the horizontal. The ascending portion of the tuba uterina rests upon its mesovarial border and the fimbriated mouth of the tube is in contact with its medial surface When enlarged the ovary may be felt through the lateral wall of the vagina and, better, through that of the rectum. Its position with regard to the surface may be indicated by a point midway between the anterior superior spine of the ilium and the symphysis pubis or the opposite pubic tubercle.

Ligaments.—In addition to its attachment to the broad ligament through the mesovarium, the ovary is also connected to the side of the uterus by the *ovarian ligament* [lig. ovarii proprium] (figs. 1038, 1040), a band of connective tissue with which numerous smooth muscle-fibers are intermingled. It lies between the two layers of the broad ligament, on the boundary line between the mesosalpinx and the mesometrium, and ex ends from the uterine pole of the ovary to the side of the uterus. Here it is attached just below the origin of the tuba uterina and above the point of attachment of the round ligament of the uterus, with which it is primarily continuous. Another ligament, termed the *suspensory ligament* of the ovary (figs. 1041, 1046), extends laterally between the two layers of the broad ligament, from the tubal extremity of the ovary to the pelvic walls, forming the lateral portion of the free boundary of the broad ligament. It is formed chiefly by the vessels and nerves (ovarian) passing to and from the ovary, and from the point where it meets the lateral pelvic wall it may be traced upward for some distance upon the posterior wall of the abdomen, behind the peritoneum, which it elevates into a more or less distinct fold, whose lateral wall on the right side becomes continuous above with the peritoneum lining the subcecal fossa.

Size.—The size of the ovary varies considerably, that of the right side being as a rule somewhat larger than that of the left. The length may be anywhere from 2.5 to 5.0 cm., the breadth about half the length and the thickness half the breadth. Its average weight in the adult is from 6.0 to 8.0 grams., but in old age it may fall to 2.0 grams.

Structure.—The ovary is covered by a layer of columnar epithelium which is continuous with the peritoneal epithelium along the line of the attachment of the mesovarium; the ovary consequently is not covered by peritoneum, but is rather to be regarded as a local thickening of the peritoneum. It is supported by a network of connective tissue, in which smooth muscle-fibers also occur, which is known as the *stroma*. The more central portions of this are largely occupied by blood-vessels but in the cortical portions are multitudes of immature ova, surrounded by their follicle-cells [folliculi oophori primarii]; and also numbers of cavities of various sizes, lined with follicle-cells and filled with fluid, each containing an ovum [ovulum] in a more or less advanced stage toward maturity. These are the *Graafian follicles* [folliculi oophori vesiculosi (Graafi)], and as they ripen they increase in diameter and approach the surface, upon which they may form marked prominences (fig. 1039). When mature the follicles burst, allowing the escape of the ovum, and the follicle becomes transformed into a *corpus luteum*. This in turn is later replaced by scar-tissue, forming a *corpus albicans*. If the ovum becomes fertilized and pregnancy results, the corpus lutem becomes larger and persists longer.

Epoophoron and paroophoron.—Closely associated with the ovaries are two rudimentary organs situated between the layers of the mesosalpinx and representing remains of the mesonephros of the embryo. The larger of these is the *epoophoron* (fig. 1042). It consists of a longitudinal duct [ductus epoophori longitudinalis (Gartneri)], lying parallel with the tuba uterina and closed at either extremity, and also 10–15 transverse ducts [ductuli transversi] which open into the longitudinal duct. It is the remains of the upper or reproductive portion of the mesonephros and therefore is the homolog of the epididymis of the male. In addition there is frequently to be found in the neighborhood of the epoophoron and close to the mouth of the tuba uterina one or more stalked, oval cysts, the *appendices vesiculosi* (*hydatids of Morgagni*), which may reach the size of a small pea.

The other rudimentary organ is the *paroophoron*. It is much smaller than the epoophoron and usually disappears before adult life, but when present consists of a small group of coiled tubules, more or less distinct, representing a portion of the excretory part of the mesonephros. Its equivalent in the male is therefore the paradidymis.

Vessels and nerves.—The chief *artery* is the ovarian, which together with the ovarian veins and lymphatics passes to the ovary in the suspensory ligament. An additional blood supply is furnished by the ovarian branch of the uterine artery. The *veins* follow the course of the arteries. As they emerge from the hilus they form a well-developed plexus (*pampiniform plexus*) between the layers of the mesovarium. Smooth muscle-fibers occur in the meshes of the plexus and the whole structure has much the appearance of erectile tissue. The *lymphatics* accompany the blood-vessels and terminate in the lumbar nodes. *Nerves* pass to the ovary with the ovarian artery from the ovarian plexus and from the hypogastric plexus.

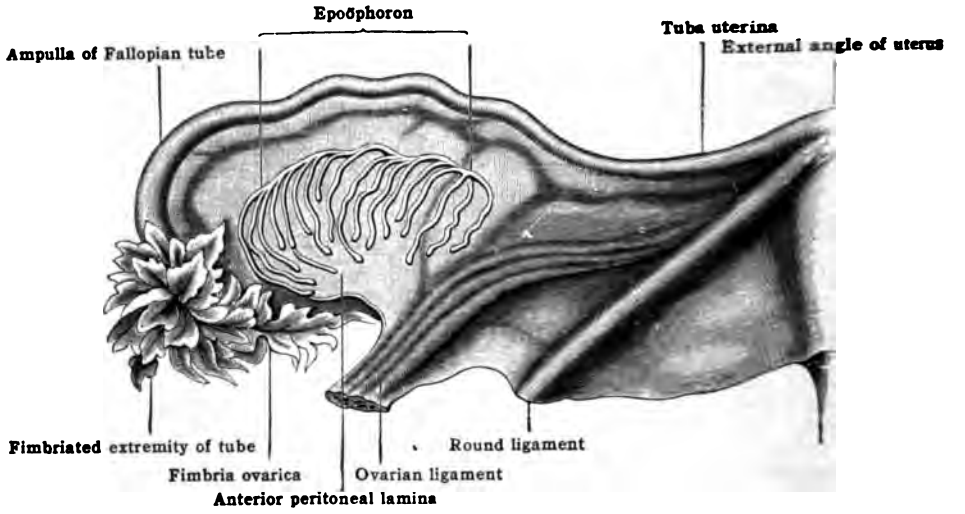
2. The Uterine Tubes

The **uterine** or **Fallopian tubes** [tubæ uterinæ] (figs. 1038 to 1042) serve to convey the ova to the uterus. They are two trumpet-shaped tubes, continuous with the superior angles of the uterus and running in the superior border of the broad ligament (mesosalpinx) to come into relation with the ovaries distally. Each tube opens proximally into the uterine cavity and distally communicates with the pelvic portion of the peritoneal cavity by a funnel-shaped mouth, the

ostium abdominale, which under normal conditions is closely applied to the surface of the ovary, so as to receive the ova as they are expelled from the Graafian follicles. Each tube is from 7 to 14 cm. in length and consists of a narrow straight portion, the **isthmus,** immediately adjoining the uterus, followed by a broader more or less flexuous portion, the **ampulla,** which terminates in a funnel-like dilation, the **infundibulum.** The margins of the infundibulum are fringed by numerous diverging processes, the **fimbriæ,** one of which, the **fimbria ovarica,** is much longer than the rest and extends along the free border of the mesosalpinx to reach the tubal pole of the ovary.

From its attachment to the uterus, the course of each tube is at first almost horizontally laterally and backward until it reaches the lateral wall of the pelvis and there comes into relation with the uterine extremity of the ovary (figs. 1041, 1046). It then bends at right angles and passes upward along the meso-

FIG. 1042.—THE BROAD LIGAMENT AND ITS CONTENTS, SEEN FROM THE FRONT. (After Sappey.)



varial border of the ovary until it reaches its tubal extremity, where it curves downward and backward so that the mouth of the infundibulum and the fimbriæ rest upon the medial surface of the ovary.

Structure.—The tubes occupy the upper free edge of the mesosalpinx and are therefore enclosed within a *peritoneal covering* [tunica serosa] except a small strip along their lower surface (fig. 1039), and hence a rupture of one of them may lead to the escape of its contents either into the peritoneal cavity or into the subserous areolar tissue between the two layers of the broad ligament. At the margins of the infundibulum and the borders of its fimbriæ the peritoneal epithelium becomes directly continuous with the mucous membrane lining the interior of the tube. The *subserous areolar* tissue [tunica adventitia] in the immediate vicinity of the tube is lax and contains the blood-vessels and nerves by which the tube is supplied; it forms a loose connection between the peritoneum and the *muscular wall* [tunica muscularis] of the tube. This consists of two layers of smooth muscle-fibers, an outer longitudinal and an inner circular layer, and reaches its greatest development toward the uterine end of the tube. The inner layer [tunica mucosa] of the tube is lined by a columnar ciliated epithelium which is raised into numerous folds, simple in the region of the isthmus, but becoming higher and more complex in the ampulla, where, in transverse sections, the lumen seems to have a labyrinthine form. The beat of the cilia is toward the uterus.

Vessels and nerves.—The *arteries* of the tubes are derived from the ovarian and uterine, each of which gives off a tubal branch, which passes between the two layers of the mesosalpinx, the one medially and the other laterally, and anastomose to form a single stem. The *veins* accompany the arteries. The *lymphatics* accompany those from the ovary and fundus uteri and terminate chiefly in the lumbar nodes (fig. 627). The *nerves* of the ampulla are given off from the branches passing to the ovary, while those of the isthmus come from the uterine branches.

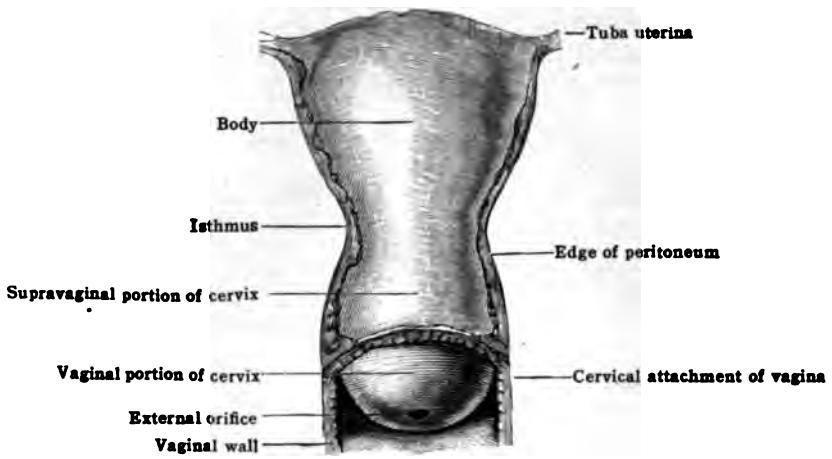
3. THE UTERUS

The **uterus** (figs. 1043 to 1047) is an unpaired organ, situated between the two layers of the broad ligament and communicating above with the uterine tubes and

below with the vagina. It is pyriform in outline, although flattened anteroposteriorly (figs. 1043, 1044) and it is divided into two main portions, the **body** [corpus uteri] and the **cervix,** by a transverse constriction, the **isthmus.**

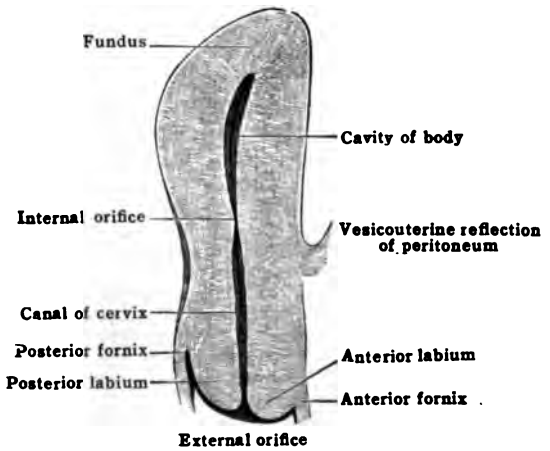
The **body** is the portion above the isthmus and in adults, especially in women who have borne children, is much larger than the cervix, although the reverse is the case in children. At puberty the two parts are about equal in size. The **anterior** or *vesical surface* facies vesicalis] is almost flat (fig. 1044), while the **pos-**

FIG. 1043.—THE POSTERIOR SURFACE OF THE UTERUS. (After Sappey.)



terior or *intestinal surface* [facies intestinalis] is distinctly convex, the two surfaces meeting in well-marked rounded borders, at the upper extremities of which the tubæ uterinæ are attached. The superior portion which extends between the points of attachment of the two tubes is thick and rounded, forming what is termed the *fundus uteri.* The *cavity* [cavum uteri] of the body is flattened anteroposteriorly (fig. 1044) and has a triangular form (fig. 1045), broad above where it communicates on either side with the cavity of a uterine

FIG. 1044.—SAGITTAL SECTION OF THE VIRGIN UTERUS. (After Sappey.)

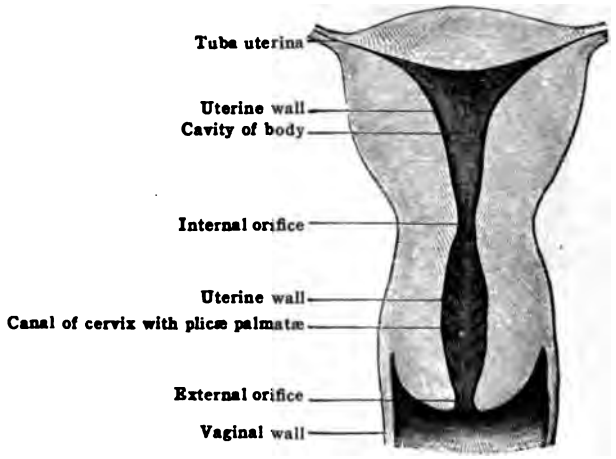


tube, but narrow below where it communicates with the cavity of the cervix. This communication, which corresponds in position to the isthmus, forms what is known as the *internal orifice* [orificium internum] (internal os uteri).

The **cervix** is more cylindrical in form, though slightly expanded in the middle of its length, and is divided into a *supravaginal* [portio supravaginalis] and a *vaginal portion* [portio vaginalis] by the attachment to it of the vagina (fig. 1043). The line of this attachment is oblique, about one-third of the anterior surface of

the cervix and about one-half of the posterior surface belonging to the vaginal portion. At the lower extremity of the cervix is the ***external orifice*** [orificium externum] (external os uteri), which is round or oval before parturition has taken place and is bounded by two prominent ***labia***, anterior and posterior, the anterior [labium anterius] being shorter and thicker than the posterior [labium posterius] and reaching a lower level (figs. 1044, 1046). In women who have borne children the external orifice assumes a form more like a transverse slit, and the labia become notched and irregular. The cavity known as the ***canal of the cervix*** [canalis cervicis] is fusiform in shape, and extends from the internal to the external orifice. On its anterior and posterior walls are folds known as the ***plicæ palmatæ*** (fig. 1045), consisting of a median longitudinal ridge from which shorter elevations extend laterally and slightly upward. These are most distinct in young individuals and are apt to become obliterated by parturition.

FIG. 1045.—FRONTAL SECTION OF THE VIRGIN UTERUS. (After Sappey.)



Position and relations.—The direction of the axis of the uterus is apparently variable within considerable limits, not only in different individuals, but also in any one individual in correspondence with the degree of distention of the bladder anteriorly and of the rectum posteriorly. In what may be regarded as the typical condition (fig. 1046) the external orifice lies at about the level of the upper border of the symphysis pubis and in the plane of the spines of the ischia. From this point the axis of the cervix is directed upward and slightly forward, the lower level of the anterior labium being thus brought about. The entire uterus is, accordingly, anteverted, and, furthermore, the body is bent forward (anteflexed) upon the cervix at the isthmus, the axis of the two portions making an angle, open anteriorly, of from 80° to 120°. Frequently, also, the body is slightly inclined either to the right or to the left.

The anterior surface of the uterus rests upon the upper and posterior surfaces of the bladder (figs. 1041, 1046), from which the body is separated by the uterovesical pouch of peritoneum. The anterior layer of the broad ligament as it passes over the anterior surface of the uterus forms the posterior wall of this pouch and is reflected forward to the superior surface of the bladder at about the level of the isthmus (figs. 1044, 1046), so that the whole of the anterior wall of the cervix is below the floor of the pouch and is separated from the posterior surface of the bladder only by connective tissue. Posteriorly, however, the peritoneal covering of the uterus, which here forms the anterior wall of the rectouterine pouch (of Douglas), extends down as far as the uppermost portion of the vagina and consequently invests the entire surface of the uterus, whose convex posterior wall is thus separated from the rectum by the rectouterine pouch (figs. 1041, 1046). Coils of the small intestine rest upon the posterior surface of the body and may occasionally be interposed between the cervix and the rectum. An important relation is that of the ureters to the cervix; these ducts, as they pass to the bladder, running parallel with the cervix at a distance of from 8 to 12 mm. from it.

Ligaments.—The *broad ligament* between whose layers the uterus is situated has already been described (p. 1297). In addition there is attached to each border of the uterus, immediately below the point of attachment of the ovarian ligament, the *ligamentum teres* (round ligament) (figs. 1041, 1042), which is a fibrous cord

FIG. 1046.—MIDSAGITTAL SECTION OF THE FEMALE PELVIS. (Spalteholz.)

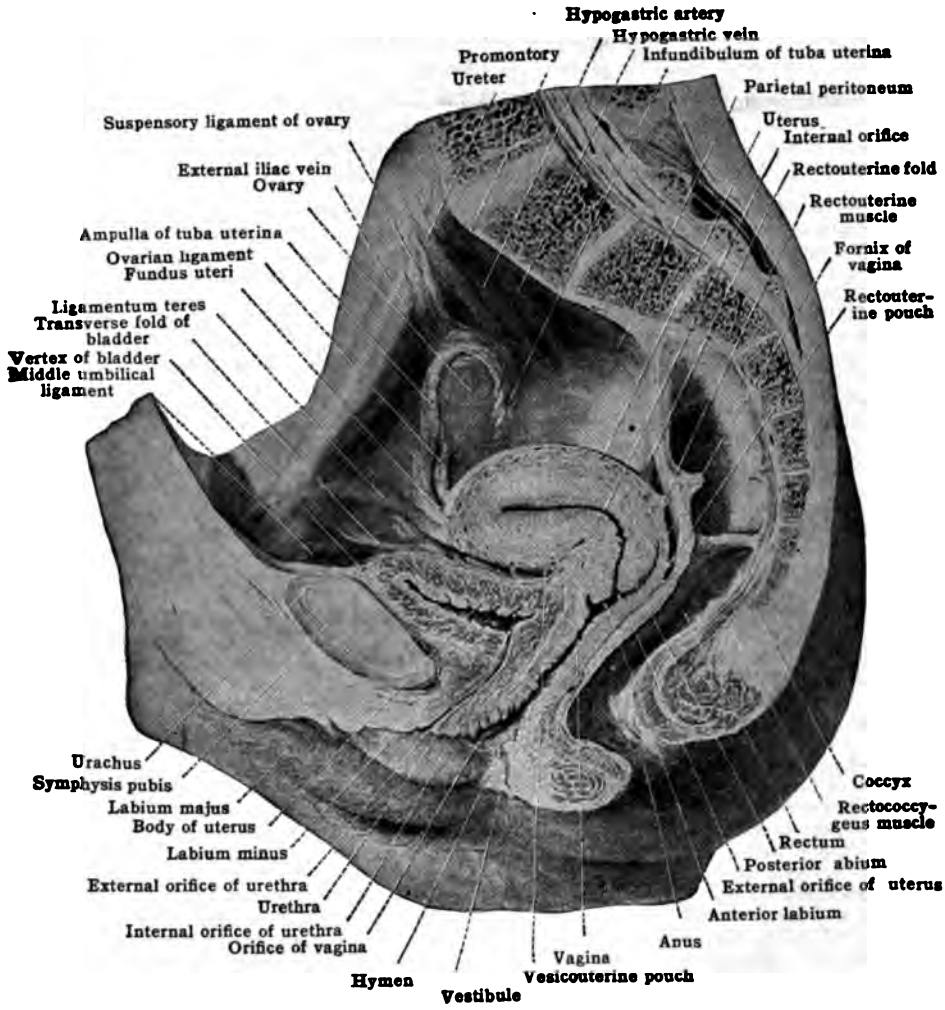


FIG. 1047.—SECTION OF THE PELVIS SHOWING THE LIGAMENTS OF THE UTERUS.

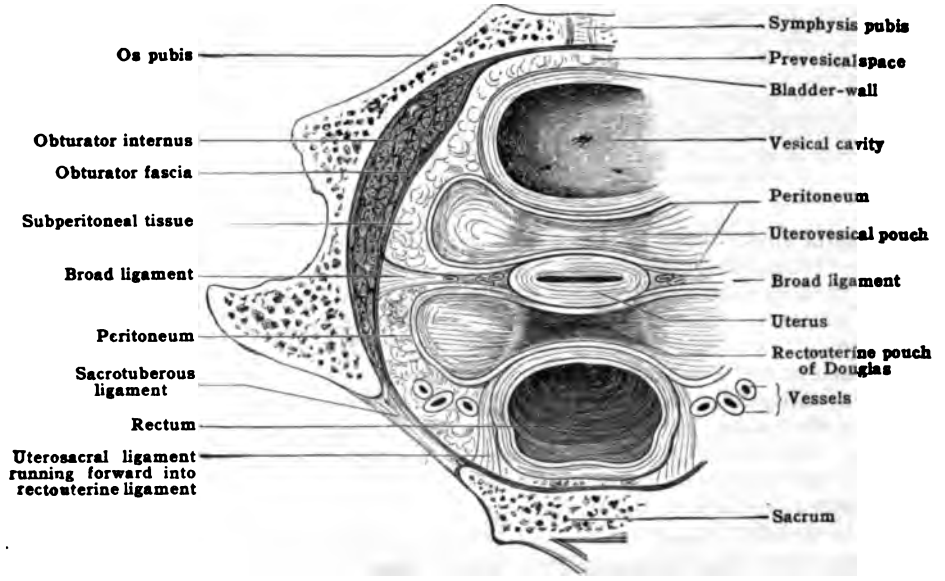


containing smooth muscle-tissue. It extends downward, laterally and forward between the two layers of the mesometrium toward the abdominal inguinal ring, and, traversing this and the inguinal canal, it terminates in the labium majus by becoming continuous with its connective tissue.

It is accompanied by a funicular branch of the ovarian artery and a branch from the ovarian venous plexus, and in the lower part of its course by a branch from the inferior epigastric artery over which it passes as it enters the abdominal ring. In its course through the inguinal canal it is accompanied by the ilioinguinal nerve and the external spermatic branch of the genitofemoral.

The *uterosacral ligaments* (fig. 1047) are flat fibromuscular bands which extend, one on each side, from the upper part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac articulation. They produce the *rectouterine folds* (fig. 1041) of peritoneum, which form the lateral boundaries of the mouth of the rectouterine pouch (of Douglas) and their muscle-fibers [m. rectouterinus] are continuous at one extremity with the muscular tissue of the uterus and at the other with that of the rectum. The anterior ligament is the vesicouterine fold of peritoneum which is reflected on the bladder from the front of the uterus. The posterior ligament is the rectovaginal fold of peritoneum which is reflected on the front of the rectum from the back of the posterior fornix of the vagina.

Structure.—The portion of the broad ligament that invests the uterus forms the serous covering [tunica serosa] of the organ and is sometimes termed the *perimetrium*. Over the fundus and the greater portion of the body it is thin and firmly adherent to the subjacent muscular substance of the uterus, so that it cannot readily be separated. Over the posterior surface of the cervix and the lower part of the anterior surface of the body, however, it is thicker, and is separated from the muscular substance by a layer of loose connective tissue, the *parametrium*, which also extends upward along the sides of the uterus between the two layers of the broad ligament, with whose subserous areolar tissue it is continuous. Owing to this disposition of the parametrium the whole of the cervix may be amputated without encroaching upon the peritoneal cavity.

The main mass of the uterus is formed by the muscle tissue [tunica muscularis] or *myometrium*, whose fibers have a very complicated arrangement. Two principal layers may be distinguished, an outer, weak one, composed partly of longitudinal fibers continuous with those of the tubæ uterinæ, and of the round and uterosacral ligaments, and a much stronger inner one, whose fibers run in various directions and have intermingled with them in the body of the uterus large venous plexuses. The inner surface of the myometrium is lined by a mucous membrane [tunica mucosa] or *endometrium*, which has a thickness of from 0.5 to 1.0 mm. and is composed of tissue resembling embryonic connective tissue, bearing upon its free surface a single layer of ciliated columnar epithelium. On account of its structure the tissue is rather delicate and friable, and numerous simple tubular glands, which open into the cavity of the uterus, traverse its entire thickness. In the cervix the mouths of some of the glands may become occluded, producing retention cysts, which appear as minute vesicles projecting from the surface between the plicæ palmatæ; they are known as *ovula Nabothi*, after the anatomist who first described them.

Vessels and nerves.—The principal *artery* of the uterus is the uterine, whose terminal portion ascends along the lateral border of the uterus in a tortuous course through the parametrium (fig. 531), giving off lateral branches to both surfaces of the uterus. Above, it anastomoses with the ovarian artery, which thus forms an accessory source of blood supply during pregnancy. The *veins* (fig. 571) form a plexus that is drained by the ovarian and uterine veins, a communication with the inferior epigastric being also made by way of the vein accompanying the round ligament. The *lymphatics* from the greater portion of the body pass to the iliac nodes; those of the fundus accompany the ovarian vessels to the lumbar nodes. A vessel also accompanies the round ligament to terminate in one of the superficial inguinal nodes. The lymph-vessels from the cervix terminate in the external iliac, hypogastric and lateral sacral nodes. The *nerves* of the uterus come from two sympathetic ganglia, situated one on either side of the cervix, whence they are termed the cervical ganglia, and forming part of the *plexus uterovaginalis*. Branches pass to the ganglia from the hypogastric plexus and also from the second, third and fourth sacral nerves.

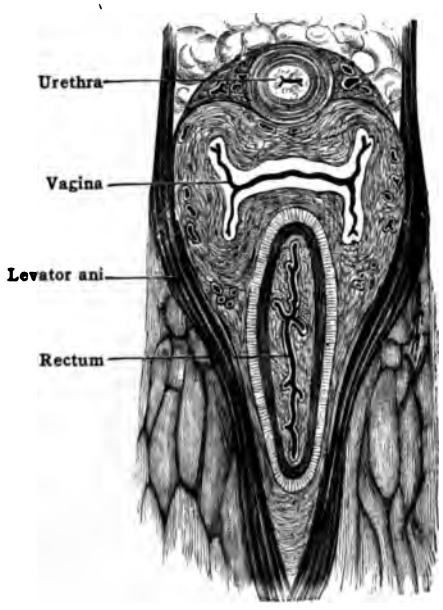
4. The Vagina

The **vagina** (figs. 1046, 1047) is a muscular, highly dilatable canal lined by mucous membrane, and extends from the uterus to the external genitalia, where it opens to the exterior. Its long axis is practically parallel with that of the lower part of the sacrum and it therefore meets the cervix uteri at a wide angle which is open anteriorly. Its anterior wall is, accordingly, somewhat shorter than the posterior, measuring 6.0–7.0 cm., while the posterior one is about 1.5 cm. longer. It becomes continuous with the cervix uteri some distance above the lower extremity of that structure (fig. 1043), which thus projects into the lumen of the vagina; and there is so formed a narrow circular space between the wall of the vagina and the vaginal portion of the cervix uteri. The roof of the space is formed by the reflection of the vagina upon the cervix and is termed the *fornix*. Owing to the greater length of the posterior wall of the vagina the portion of the

circular space below the posterior fornix is considerably deeper than that below the anterior.

In its ordinary condition the lumen of the vaginal canal is a fissure, which in transverse section resembles the form of the letter **H** with a rather long transverse bar (fig. 1048). On both the anterior and the posterior wall there is in the median line a well-marked longitudinal ridge, the *columna rugarum*, which is especially distinct in the lower part of the anterior wall, where it lies immediately beneath the urethra and forms what is known as the *urethral carina*. From both columnæ other ridges pass laterally and upward on either side, forming the *rugæ vaginales*. Both these and the columnæ diminish in distinctness with advance in age and with successive parturitions. Toward its lower end the vagina traverses the urogenital diaphragm, being much less dilatable in this region than elsewhere, and it opens below into the vestibule of the external genitalia. Its orifice is partially closed by a fold of connective tissue, rich in blood-vessels, and lined on both surfaces by mucous membrane. This structure, known as the

FIG. 1048.—HORIZONTAL SECTION OF VAGINA AND ADJACENT STRUCTURES. (After Henle.)



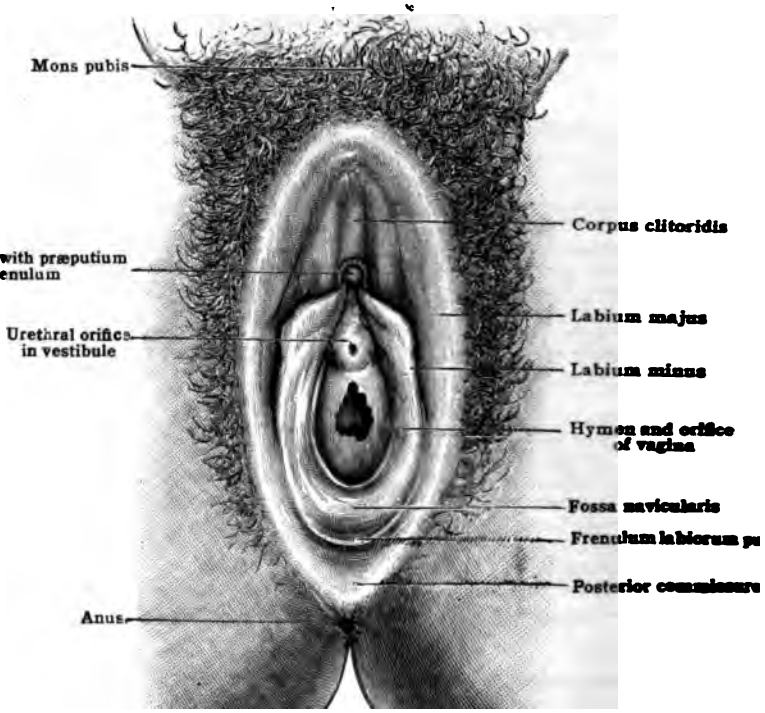
hymen, has usually a somewhat semilunar form, covering the posterior border of the orifice, but it may take the form of a circular curtain pierced by one or several apertures.

The hymen varies greatly in strength and development and although it is nearly always ruptured by the first act of sexual congress, it may remain unbroken until parturition. Rarely it takes the form of a complete imperforate curtain and may necessitate a surgical operation at the commencement of the menstrual periods. After rupture the remains of the hymen persist as small lobed or wart-like structures, the *carunculæ hymenales*, around the vaginal orifice.

Relations.—The uppermost part of the posterior wall of the vagina is in relation with the peritoneum forming the floor of the rectouterine pouch (of Douglas), but elsewhere the canal is entirely below the floor of the peritoneal cavity. *Posteriorly* the vagina rests almost directly upon the rectum (figs. 1046, 1048), and the contents of that viscus may be readily felt through the vaginal wall. *Anteriorly* it is in intimate relation with the urethra and the posterior wall of the bladder (figs. 1046, 1048). *Laterally* it is crossed obliquely in its upper portion by the ureters (fig. 531) as they pass to the base of the bladder, and in its lower two-thirds by the edges of the anterior portion of the levatores ani. The *duct of Gartner*, the remains of the lower portion of the Wolffian duct may occasionally be found at the side of the upper half of the vagina as a minute tube or fibrous cord. The external orifice is surrounded by the fibers of the bulbocavernosus muscle, which may be regarded as forming a sphincter (*sphincter vaginæ*).

The female **external genitalia** [partes genitales externæ] present an el
depression, occupying the perineal region and bounded laterally by two
integument, the *labia majora* (fig. 1049). These anteriorly are continued

FIG. 1049.—THE EXTERNAL GENITALIA OF THE FEMALE.

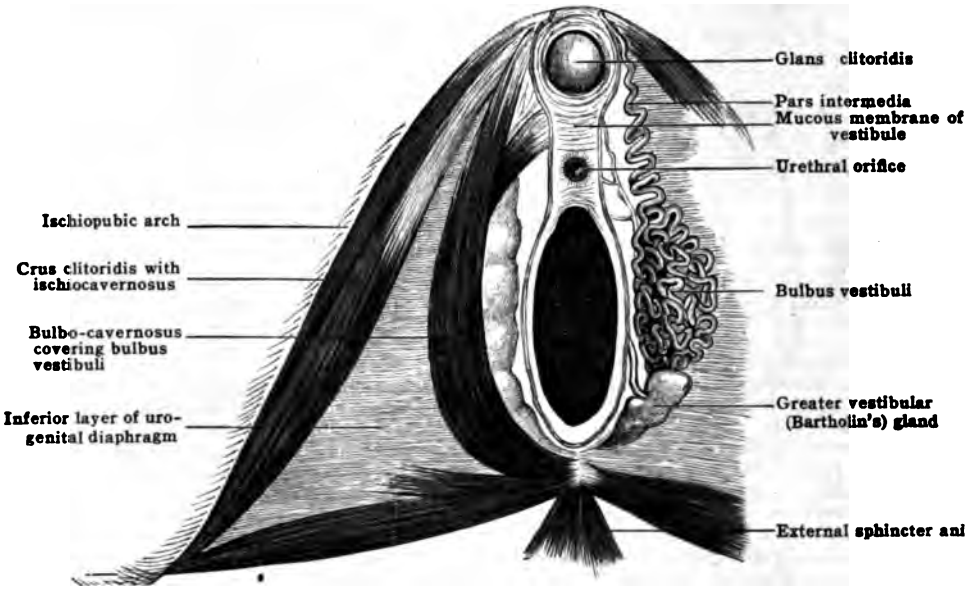


being destitute of hairs and fat. They are usually concealed by the labia majora, but are sometimes largely developed and may then project through the rima pudendi, assuming a dried and pigmented appearance.

The labia minora divide and unite anteriorly over the distal extremity of the clitoris, forming the *præputium clitoridis* in front of the clitoris, and the *frenulum clitoridis* behind it. Posterior to this they diverge and reach their greatest height, gradually diminishing as they pass backward to terminate in a slight, inconstant, transverse fold, the *frenulum labiorum pudendi*, situated just anterior to the posterior commissure of the labia majora. Anterior to the frenulum is the *fossa navicularis* of the vestibule.

The vestibule.—The space between the two labia minora is termed the *vestibule* [vestibulum]. Into its most anterior portion there projects the extremity of an erectile organ, the **clitoris** (fig. 1049), which is comparable to the penis of the male. It is, however, relatively small and is not perforated by the urethra, which lies below it. It is composed of two masses of erectile tissue, the *corpora cavernosa clitoridis*, which differ from the corresponding structures of the penis only in size. They are attached posteriorly to the rami of the pubis by the *crura clitoridis* (fig. 1050), and as they pass forward they converge and meet to form the body of the organ [corpus clitoridis], which, beneath the symphysis pubis, bends sharply

FIG. 1050.—DIAGRAMMATIC REPRESENTATION OF THE PERINEAL STRUCTURES IN THE FEMALE.



upon itself and passes posteriorly beneath the anterior commissure of the labia majora. Distally the corpora cavernosa abut upon another mass of erectile tissue, which fits like a cap over their extremities; it is formed by an anterior prolongation of the bulbi vestibuli and is termed the *glans clitoridis* (figs. 1049, 1050), being comparable to the glans penis, from which it differs chiefly in not being perforated by the urethra.

A short distance posterior to the glans clitoridis is the *external urethral orifice* [orificium urethræ externum], situated upon the summit of a slight papilla-like elevation. Lateral to this orifice are sometimes found the openings, one on either side, of two elongated slender ducts, the *paraurethral ducts* (ducts of Skene). More posteriorly is the orifice of the *vagina* [orificium vaginæ], partially closed in the virgin by the *hymen*. Lateral to this, in the angles between the hymen and the labium minus on either side, is the opening of the greater vestibular gland, while the lesser glands open at various points on the floor of the vestibule, sometimes at the bottom of more or less distinct depressions.

Beneath the floor of the vestibule and resting upon the superficial layer of the urogenital diaphragm are two oval masses of erectile tissue, the *bulbi vestibuli* (fig. 1050), homologous with the corpus cavernosum urethræ of the male. They consist principally of a dense venous network, enclosed within a thin investment of

connective tissue. From the main mass of each bulbus a slender prolongation the *pars intermedia*, extends anteriorly past the side of the urethra, to join the glans clitoridis.

The *greater vestibular glands* [gl. vestibularis major (Bartholini)] or glands of Bartholin (fig. 1050) correspond to the bulbourethral glands of the male. They are two small, compound tubular glands, situated one on either side immediately posterior to the bulbi vestibuli.

The single *duct* of each gland opens on the floor of the vestibule in the angle between the hymen and the orifice of the vagina and a little posterior to the midtransverse line of the latter. Numerous small tubular glands occur in the integument forming the floor of the vestibule; they are termed the *lesser vestibular glands* and are especially developed in the interval between the urethral and vaginal orifices.

The **muscles** of the female external genitalia (fig. 1050) correspond to the perineal muscles of the male (see Section IV). There are two *transverse perineal* muscles, which have the same relations as in the male, and two *ischiocavernosi*, which are related to the crura clitoridis just as those of the male are to the crura penis. The *bulbocavernosi*, however, present somewhat different relations, each being band-like in form, arising from the central point of the perineum and extending forward past the orifice of the vagina, over the greater vestibular gland and the bulbus, to form with its fellow of the other side a tendinous investment of the body of the clitoris. The two muscles act as a sphincter to the vagina and are sometimes termed the *sphincter vaginæ*.

The urethra.—The urethra of the female [urethra muliebris] (figs. 1046, 1048) corresponds only to the prostatic and membranous portions of the male, and is a relatively short canal, measuring from 3.0 to 4.0 cm. in length. At its origin from the bladder it lies about opposite the middle of the symphysis pubis and thence extends downward and slightly forward to open into the vestibule between the glans clitoridis and the orifice of the vagina. Its posterior wall is closely united with the anterior wall of the vagina, especially in the lower part of its course where it forms the *urethral carina* of the vaginal wall; laterally and anteriorly it is surrounded by the pudendal plexus of veins. Above it is separated anteriorly from the symphysis pubis by the lower part of the prevesical space of Retzius.

Structure.—Its walls are very distensible, and are lined by a mucous membrane with numerous longitudinal folds, one of which on the posterior side is more prominent and is termed the *crista urethralis*. The mucosa contains numerous small glands [gl. urethrales], a group of which on each side is drained by the inconstant *ductus paraurethralis*, opening into the vestibule as mentioned above. External to the loose submucosa is a sheet of smooth muscle, whose fibers are arranged in an outer circular and an inner longitudinal layer, a rich plexus of veins lying betwen the two and giving the entire sheet a somewhat spongy appearance. The circular fibers are especially developed at the vesical end of the canal, forming there a strong sphincter, and striped muscle-fibers, derived from the bulbocavernosus form a sphincter around its vestibular orifice. The female urethra differs from that of the male in not being enclosed within a prostate gland; but what are probably rudiments of this structure are to be found in the groups of urethral glands drained by the paraurethral ducts.

Vessels and nerves.—The *arteries* supplying the external female genitalia are the internal and external pudendals, and the *veins* terminate in corresponding trunks. The *lymphatics*, which are very richly developed, drain for the most part to the inguinal nodes; those from the urethra pass to the iliac nodes. The *nerves* are partly sympathetic and partly spinal; the former are derived from the hypogastric plexus, the latter principally from the pudendal, the anterior portions of the labia majora being supplied by the ilioinguinal and the external spermatic branch of the genitofemoral.

DEVELOPMENT OF THE REPRODUCTIVE ORGANS

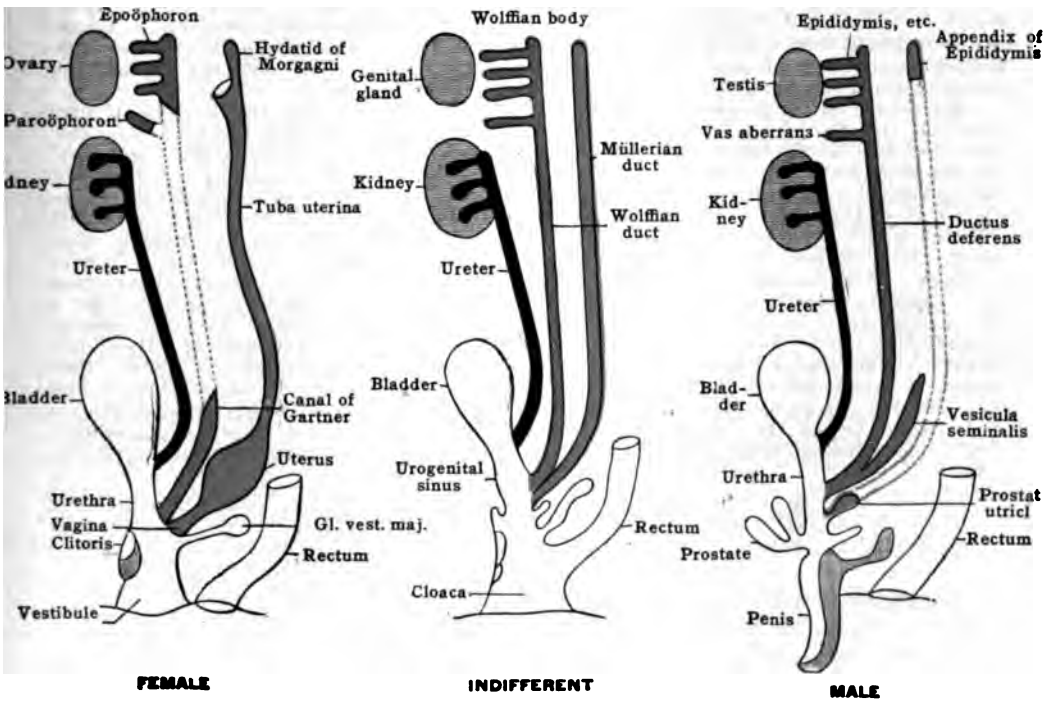
An account of the development of the urogenital tract in the two sexes is given in the section on DEVELOPMENTAL ANATOMY (pp. 52, 53). As also mentioned on p. 50, during development a transitory excretory organ, the **mesonephros** or **Wolffian body**, reaches a high degree of development, and its duct, the **Wolffian duct**, opens into a **cloaca** or **common outlet** for the intestinal and urinary passages. The mesonephros forms a marked projection from the dorsal wall of the abdomen into the body-cavity, and on the medial surface of the peritoneum which covers it a thickening appears which is termed the **genital ridge**. The upper part of this ridge becomes the ovary or testis, as the case may be, while the remainder of it becomes the ovarian and round ligaments in the female and the gubernaculum testis in the male.

As the ovary or testis develops, the tubules of the upper part of the **Wolffian body** enter into relation with it, forming, indeed, in the case of the testis, a direct union with the seminiferous tubules. The Wolffian body then becomes divisible into a reproductive and an excretory portion, and, when the metanephros or permanent kidney develops, the latter portion degenerates, leaving only a few rudiments, such as the paroöphoron in the female (p 1299) and the

vas aberrans and paradidymis (p. 1286) in the male. The reproductive portion also becomes much reduced in the female, persisting as the tubules of the epoöphoron (p. 1299), but in the **male** it forms the lobules of the epididymis and serves to transmit the spermatozoa to the **Wolffian** duct.

In addition to the Wolffian duct, a second duct, the **Müllerian,** occurs in connection with the genitourinary apparatus, and, like the Wolffian duct, it opens below into the cloaca. The **history** of the two ducts is very different in the two sexes. In the **male** the Wolffian duct persists to form the vas deferens, of which the seminal vesicle is an outgrowth and the ejaculatory duct the continuation, while the Müllerian duct degenerates, its lower end persisting as the prostatic utriculus and its upper end as the appendix of the epididymis. In the **female,** on the contrary, it is the Müllerian duct which persists, its lower portion fusing with the duct of the opposite side to form the vagina and uterus, while its upper portion forms the tuba uterina. Inhibition of the fusion of the lower ends of the two Müllerian ducts gives rise to the bicornuate or divided uteri, or the bilocular uteri and vaginæ which occasionally occur. The Wolffian duct in the female almost completely disappears, persisting only as the longitudinal tube of the epoöphoron and as the rudimentary canal of Gartner (p. 1299). With the degeneration of the mesonephros, the peritoneum which covered it becomes a thin fold, having in its free edge the Müllerian duct and, on the fusion of the lower ends of the ducts, the two folds also fuse and so give rise to the broad ligament.

FIG. 1051.—DIAGRAM OF HOMOLOGIES IN UROGENITAL DEVELOPMENT.



The developmental relations of the male and female organs may be seen from figure 1051 and also from the following table:—

	MALE	FEMALE
Genital ridge	Testis	Ovary
	Gubernaculum testis	Ovarian ligament / Round ligament
Wolffian body (Mesonephros)	Head of epididymis	Epoöphoron
	Paradidymis	Paroöphoron
	Vas aberrans	
Wolffian duct	Body and tail of epididymis	Longitudinal tubule epoöphoron
	Ductus deferens	Canal of Gartner
	Ejaculatory duct	
Müllerian duct	Appendix of epididymis (?)	Uterine (Fallopian) tube
		Uterus
	Prostatic utriculus	Vagina

The development of the external organs of generation in the two sexes presents a similar differentiation from a common condition. The division of the cloaca to form a **urogenital sinus** and the terminal part of the rectum has already been noted (p. 1283). In the floor of the

	MALE	FEMALE
Urogenital sinus	Cavernous portion of urethra	Vestibule
Genital tubercle	Penis	Clitoris
Genital folds	Integument and prepuce of penis	Prepuce of clitoris and labia
Genital swellings	Scrotum	Labia majora

Inhibition of the development of the parts in the male or their over-development female will produce a condition resembling superficially the normal condition of the o sex, and constituting what is termed *pseudohermaphroditism;* or a failure of the genital to fuse may result in what is known as *hypospadias*, the cavernous portion of the urethr merely a groove on the under surface of the otherwise normal penis.

SECTION XIII

THE GLANDS OF INTERNAL SECRETION

REWRITTEN FOR THE SIXTH EDITION

BY J. F. GUDERNATSCH, PH.D.

PROFESSOR OF ANATOMY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK CITY

TO the group of the **glands of internal secretion** belong a number of rather small organs, which have certain physiological and histological features in common, although anatomically they do not compose a well defined system. These glands are located in widely scattered regions of the body and are derivatives of such different organ-systems, derived from all three embryonic layers, that in text-books of anatomy their grouping together in a separate chapter is mainly upon a physiological basis. Although each of these glands serves its specific purposes, most of them as yet little understood, their *method* of functioning seems to be rather uniform. It is also well known that at least some of these glands have definite chemical relations to each other; so that, physiologically, they doubtless form a system of interdependent units. This interdependence goes so far, that during the processes of development, growth and differentiation, the well regulated interaction of these glands brings about the formation of the normal organism. Furthermore, although without any anatomical relationship, they have, in their finer structure, certain rather striking characteristic features in common, which justify their grouping as a separate system of organs.

1. Being glandular organs, they all (with the possible exception of the interstitial cell-complex of the sex-glands) develop from epithelium. Their physiologically active stratum is therefore of an epithelial or, at least, epithelioid nature. Only one of them, the thyroid, possesses a definite, uniform arrangement of these epithelial cells, while in the other glands we find a rather irregular distribution of these cells in the form of cords, trabeculæ, clusters, etc.

2. The epithelial cells lie in very close approximation to the endothelial cells of the blood- and lymph-channels. The vascular supply of these organs is extremely abundant, the vessels in many of them forming dense sinusoidal plexuses around the epithelial structures.

3. They are *ductless glands* having no excretory duct. Their secretion is carried from the epithelial through the endothelial cells directly into the vascular channels. They are, therefore, glands of *internal* secretion. The absence of a duct, however, is probably only a secondary, phylogenetically acquired feature. We have very good reasons to believe that in the extinct vertebrates (attempts have been made to trace these glands even to the invertebrates) all these structures *did* possess an excretory duct and were thus glands of *external* secretion. In the ontogeny of some of these glands, we still see the anlage of a definite outleading canal, which, however, normally retrogresses.

After further research into the physiology of the ductless glands it will perhaps be possible to place these organs in several groups, such as: (*a*) those that exert their influence mainly upon the growing and differentiating organism; (*b*) those, the action of which is chiefly concerned in regulating the metabolic process of the body; etc. Also the different periods in the life-cycle at which these glands exert their greatest influence have to be taken into account. At present, we can say that the greater number of these glands probably serve both purposes mentioned above, either synchronously or at successive periods. In the latter instance a change of function, or the assumption of an additional function, sets in as the individual goes through the period of differentiation into that of adolescence and maturity (thyroid, hypophysis, etc.). Other glands are glands of a specific developmental period (thymus in the young, sex-gland in the adult), etc.

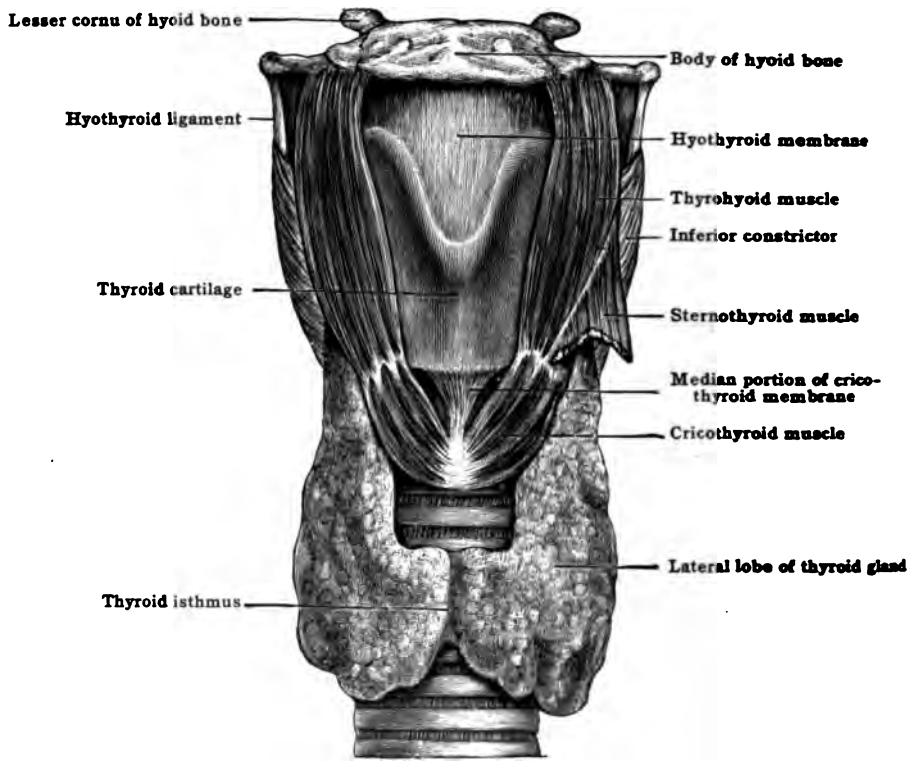
We may also say that *correlation* is most typically shown in the group (*a*) concerned in the processes of differentiation. Several glands of this group may act harmoniously, or one may supersede the work of the other. In the other group, too, the 'metabolic group' (*b*), interaction is distinctly traceable, especially when the chemical processes do not proceed satisfactorily; for instance, disturbances are shown in the hypophysis and thyroid, when the sex-gland is under strain, as in pregnancy; or disorders of the pancreatic islands and the hypophysis in disturbed carbohydrate metabolism; etc. The parathyroids and the chromaffin system seem to stand more aloof from the rest than any other of the ductless glands, although a possible rôle of the suprarenals during development cannot be excluded *a priori*.

To the system of the organs with an internal secretion must be added a number of structures provided with the same physiological mechanism, yet of no definite gross anatomical characteristics, (pancreatic islands, interstitial cell-complex of the sex-glands, corpus luteum, and organs which mainly function in another direction (sex-glands liver, digestive glands (?), placenta, mammary glands, etc.). All such structures are discussed under their respective systems.

THYROID GLAND

The **thyroid gland** [glandula thyreoidea] (fig. 1052) has approximately the form of a horse-shoe, the two lateral portions of which are usually more pronounced than the median connecting piece. These **lateral lobes** are somewhat asymmetrical in size and shape, while their connecting piece, the **isthmus,** varies considerably in size in different individuals. It may be entirely absent, or in other cases

FIG. 1052.—VENTRAL VIEW OF THE THYROID GLAND.

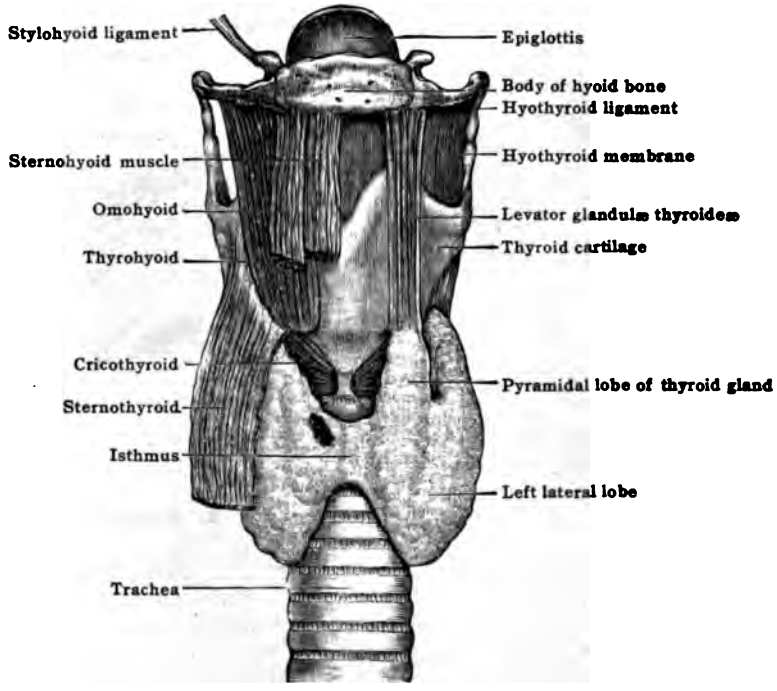


it may represent a considerable portion of the total mass of the organ. In the latter case, it may extend out into a strip which runs for a shorter or longer distance cephalad between the two lateral portions. This short lobe of the thyroid gland usually has the shape of a pyramid, the broad base being represented by the isthmus, while it tapers toward the cephalic end. It is called the **pyramidal lobe** (fig. 1053). The main lateral lobes also somewhat resemble three-sided pyramids, their bases occupying the caudal end, merging there into the isthmus, while the somewhat rounded apex forms the cephalic end. The three surfaces of each lateral lobe (fig. 1054) are: (1) the *lateral* surface, by far the largest, which is somewhat convex and is covered by certain muscles of the neck; (2) the *medial* surface, rather concave, since it is closely applied to the convex surfaces of the

thyroid, cricoid, and tracheal cartilages; and (3) the *posterior* surface, the smallest one, rather flat, facing the great vessels of the neck. The three borders of the lateral lobe are somewhat rounded off. The apex of the lobe lies more dorsally than the base.

The two lateral lobes (figs. 1052, 1053, 1055) are present in the greater number of individuals, although there may at times appear a decided asymmetry in the size and shape of these lobes. The median portion, the **isthmus,** however, is extremely variable in expansion. In a few individuals it is rudimentary or lacking entirely. When well developed (figs. 1052, 1053), it usually does not occupy an extreme caudal position, so that the shape of the entire organ is more that of an 'H' than of a horse-shoe, 'U'. Due to its relations the ventral surface of the isthmus is somewhat convex, while the dorsal one is distinctly concave. In some cases the isthmus is rather voluminous and it may then represent the greater portion of the gland (arrested morphogenesis, see below), while the lateral lobes may be small, or one or the other entirely absent.

FIG. 1053.—THYROID GLAND, WITH PYRAMIDAL LOBE AND LEVATOR MUSCLE.



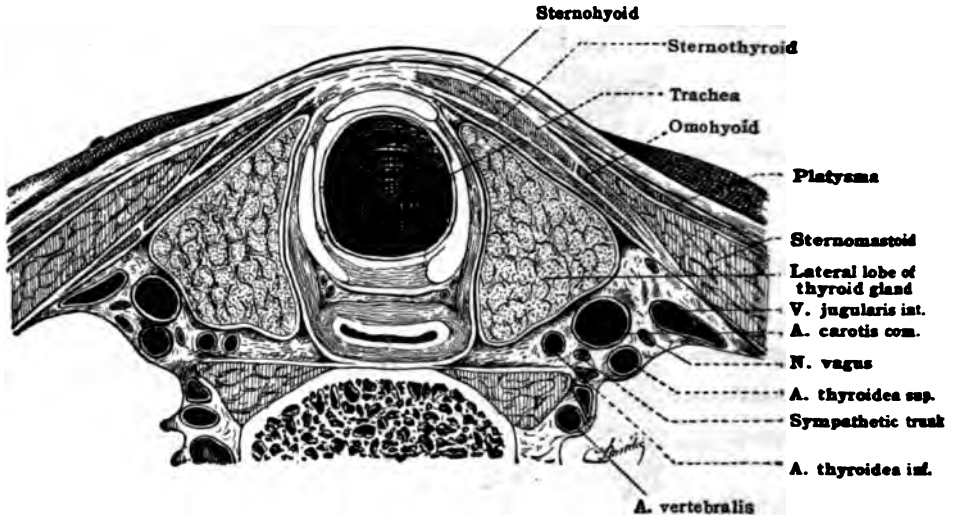
The greatest degree of variation is shown in the size and extension of the so-called **pyramidal lobe** of the thyroid gland (pyramid of L'Alouette, 1743). This pyramidal lobe (figs. 1053, 1055, 1056) usually has the shape of a rather narrow strip, broader at its basal end and tapering toward its cranial apical end. It commonly arises from the isthmus, but may at times be attached to the caudal region of either of the lateral lobes. It may extend as far craniad as the hyoid bone, although more often it ends in the neighborhood of the thyroid cartilage. It usually lies somewhat to the left of the midline and is present in about one-third of the cases.

Size.—The size and weight of the gland are subject to considerable variation. It is next to impossible to give exact measurements, since the line between normal, well developed, and abnormal, hypertrophied, glands is indefinite. In women it enlarges at puberty and is especially liable to periodical changes, its size increasing somewhat during menstruation and considerably so during pregnancy. In older persons the gland decreases in size, due to the partial replacement of the epithelial structures by connective tissue (fibrosis). Especially the pyramidal lobe seems to undergo a gradual physiological atrophy. It is more often found in children than in the adult. The length of the lateral lobes is variously given as ranging from 5 to 8 cm., the width 2 to 4 cm., the thickness 1 to 2.5 cm. The average weight of the gland is given as 34 g. with a range from 11 to 60 g. Racial and geographical differences are considerable. In women the gland is always larger and heavier than in men, a difference not apparent in infants. The gland readily becomes hypertrophied, especially in women, and is apt to undergo pathological changes (goiter or struma). A congenital struma may be found in children of affected mothers, especially in regions where endemic goiter prevails.

The **color** of the thyroid gland is reddish-brown, but may at times become rather bluish. The **consistency** is rather firm, but slightly compressible, the degree of rigidity depending on the physiological state of the gland. The surface of the gland is smooth or slightly uneven.

The thyroid gland is surrounded by a white fibrous connective tissue sheath, which is a part of, and in close connection with, the deep fascia of the neck. According to Sébileau (quoted from Sobotta), the deep fascia of the neck, near its insertion on the lateral vertebral process, gives off a layer, the so-called transverse aponeurosis of the neck. As this approaches the area of the carotid artery, jugular vein and vagus nerve, it splits into two layers, surrounding these structures as the carotid sheath. Medially to the vessels, these two layers do not re-unite; the posterior one is continued behind the pharynx, and fuses with the corresponding layer of the opposite side; the anterior, pretracheal layer forms the thyroid sheath. As it reaches the lateral margin of the gland, it splits into two secondary lamellæ, the anterior one being continued over the lateral and anterior surface of the gland, enclosing partly the inferior thyroid veins, while the posterior one is closely applied to the wall of the trachea. Thus the gland is completely surrounded by its sheath, which is more or less loosely attached to the

FIG. 1054.—CROSS-SECTION OF NECK SHOWING RELATIONS OF THE THYROID GLAND. (After Braune, from Poirier-Charpy.)



surface, so that the gland may easily be shelled out. Finer fibrous trabeculæ connect the sheath with the surface of the organ. This sheath must not be mistaken for the capsule proper of the gland, which can be torn away only by force, since its tough connective tissue is continued into the interior of the gland. There is an interval between the capsule and the sheath, which is traversed by the arteries. The veins also form plexuses in this space (figs. 1055, 1056).

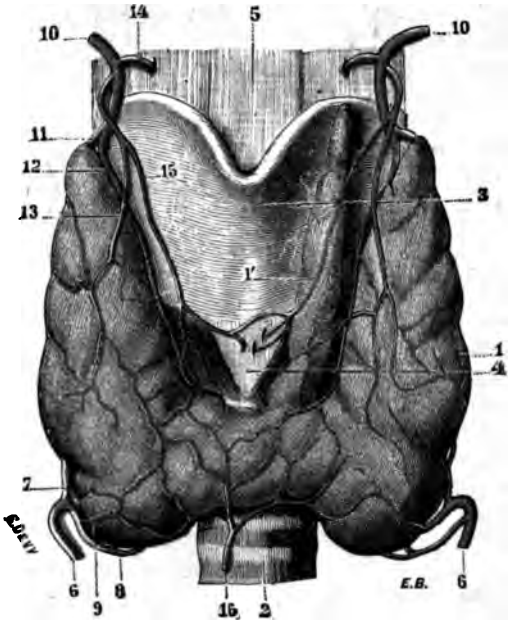
Three suspensory ligaments of the thyroid gland are described (by Gruber), attaching the dorsal surface of the fibrous sheath to the neighboring cartilages: a median, running from the ventral surface of the thyroid cartilage to the dorsal aspect of the isthmus, and two lateral ligaments, attaching the basal portions of the lateral lobes to the tracheal and cricoid cartilages. There may be a fourth ligament, connecting the cranial tip of the pyramidal lobe to the thyroid cartilage or even to the hyoid bone. A muscular band [levator glandulæ thyroideæ] may take the place of this ligament (fig. 1053). A number of other levator muscles have been described, which are simply bundles split off from the neighboring muscles, thyrohyoid, sternohyoid, constrictor pharyngis inferior, etc.

Topography.—The thyroid gland lies ventrally to the trachea in the mid-portion of the neck. A well-developed pyramidal lobe may extend into the subhyoid or even hyoid region (fig. 1056). The isthmus and pyramidal lobe occupy a ventral, superficial position, while the lateral lobes extend back into a more dorsal, deeper area. The isthmus usually covers the second to the fourth tracheal ring. It may, however, reach as high as the cricoid cartilage and then cover the cricotracheal ligament, or as low as the eighth tracheal cartilage. In the midline, the isthmus and pyramidal lobe are covered by the skin and superficial and deep (pretracheal) layers of the fascia only. The lateral lobes lie in the main on the sides of the cricoid and thyroid cartilages and may extend to the fifth or sixth

tracheal ring, about 2 cm. above the sternum. The cranial apices of these lobes may come in contact with the esophagus and pharynx. Their more dorsal position is due to the insertion on the thyroid cartilage of the sternothyroid muscle (fig. 1053). Their anterolateral surface is covered directly by this muscle: more superficially lie the thyrohyoid, omohyoid, sternohyoid, and sternocleidomastoid muscles. The medial surface is applied to the trachea and deeper in to the esophagus (fig. 1054). The position of the recurrent nerve in that region is of surgical importance. The posterior surface lies close against the carotid sheath. Sometimes the common carotid artery makes an impression on that surface. Even the vagus may come in contact with it. The attachment to the pharynx, esophagus and larynx is rather loose, while that to the trachea, especially laterally, is firmer.

Blood-vessels.—The blood-supply of the thyroid gland is extremely abundant. There are usually four arteries (fig. 1055) present: the two superior thyroid arteries, branches of the external carotid artery, and two inferior thyroid arteries, branches of the subclavian artery, or of the thyrocervical trunk. Not uncommonly, a fifth unpaired artery is present, the *thyroidea ima* artery.

FIG. 1055—ARTERIES OF THE THYROID GLAND, ANTERIOR VIEW. 1. Lateral lobe; 1, pyramidal lobe; 2, trachea; 3, thyroid cartilage; 4, cricothyroid membrane; 5, hyothyroid membrane; 6, 7, 8, 9, inferior thyroid artery and branches; 10, 11, 12, 13, 14, 15, superior thyroid artery and branches; 16, thyroidea ima. (Testut and Jacob.)



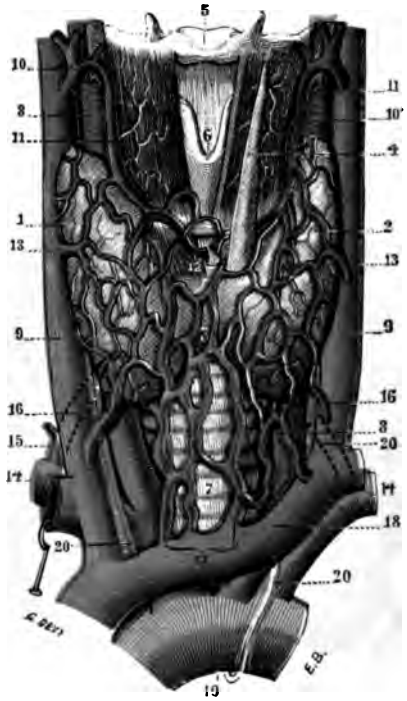
The **superior thyroid artery** (figs. 491, 1055) usually divides into three branches, one coursing over the anterolateral surface, one running along the anterior border to the isthmus, and there anastomosing with its mate of the opposite side, and one spreading over the upper part of the medial surface. The pyramidal lobe is supplied from the second branch. The **inferior thyroid artery** (figs. 491, 1055, 1057) usually has two branches, one running along the inferior border of the lateral lobe to the dorsal aspect of the isthmus and there anastomosing with its partner from the opposite side, the other one supplying the lower region of the dorsal and medial surfaces of the lateral lobes. A third one may establish an anastomosis with the superior branches. In the region of the isthmus there is usually found an anastomosis of all four or five thyroid arteries. The unpaired **thyroidea ima** artery arises from the aortic arch or the innominate artery, ascends ventrally to the trachea somewhat on the right side, until it reaches the isthmus, where it anastomoses with the others (figs. 487, 1055). These arteries send their branches directly into the substance of the gland, the primary ones running in the connective tissue septa, which extend from the capsule into the interior.

The **veins** emerging from the gland form on the anterolateral surface a veritable plexus (fig. 1056) from which arise: the **superior th roid veins,** tributaries to the internal jugular or more often to the common facial vein; the **median thyroid veins,** tributaries to the internal jugular vein; the **inferior thyroid veins,** draining lower down into the jugular or innominate vein; and occasionally, the unpaired **thyroidea ima vein,** draining into the left innominate vein or the venous angle.

Lymphatics.—Of great importance is the lymph-circulation of the thyroid gland, corresponding to the inferior and superior blood-supply. Bartels describes a superior and inferior area of lymphatic drainage, each area supplying medial and lateral channels. The medial superior channels drain the cranial border of the isthmus and the medial surfaces, the lateral superior channels drain the ventral and dorsal surfaces. Both groups run into the deep cervical lymph-nodes. The medial inferior channels drain the isthmus and medial portions of the lateral lobes and run into the pretracheal and paratracheal nodes; the lateral inferior vessels drain the lateral inferior portions and run into the supraclavicular nodes. The lymph-nodes of the thyroid gland, which are surgically important, are, therefore: the deep cervical nodes (superior, as well as supraclavicular), the prelaryngeal, the pretracheal and paratracheal, sometimes also the upper mediastinal nodes. (See p. 75.)

Nerves.—The nerve-supply of the thyroid gland comes mainly from the middle and inferior cervical ganglia of the sympathetic system. The fibers follow the arteries and form a *superior* and an *inferior thyroid plexus*. Fibers have also been described coming from the recurrent, superior and inferior laryngeal, the glossopharyngeal, vagus and hypoglossal nerves.

FIG. 1056.—VESSELS OF THE THYROID GLAND, ANTERIOR VIEW. 1, 2, 3, Lateral lobes and isthmus; 4, pyramidal lobe; 5, hyoid bone; 6, thyroid cartilage; 7, trachea; 8, common carotid; 9, internal jugular; 10, thyro-linguo-facial vein; 11, superior thyroid artery; 12, inferior laryngeal vessels; 13, middle thyroid vein; 14, subclavian artery; 15, inferior thyroid artery; 16, inferior lateral thyroid veins; 17, inferior medial thyroid veins; 18, left innominate vein; 19, aortic arch; 20, vagus nerve. (Testut.)



Development.—The thyroid gland arises (see p. 55) as a ventral median diverticulum of the pharynx (figs. 37A, 41), cranial to the second branchial arches. Grosser has shown that the thyroid anlage is unpaired and that all previous reports as to the paired, lateral origin of the gland have to be discarded. The epithelial diverticulum is first seen in human embryos of about 1.4 mm. length, with 5 or 6 somites. It is usually a hollow diverticulum, which shows a slight terminal swelling. In embryos of 2.5 mm. (23 somites), this bud begins to lose its connection with the pharyngeal tube. The duct, *thyreoglossal duct*, disintegrates, while the vesicle transforms into a solid mass, which lengthens out in a transverse direction, until it forms a strip of epithelial tissue running across the midline and showing a distinct swelling at either end, the beginning of the lateral lobes. The point of origin of the epithelial duct moves somewhat caudad, until it comes to lie between the second gill-bars. In the development of the tongue, this region is taken up into the root of the latter, so that, ultimately, a slight depression, *foramen cecum*, on the back of the tongue marks the original opening of the thyroglossal duct, which may occasionally persist in the adult as the *ductus lingualis*. This duct normally is soon transformed into a solid cord of cells running ventrally to the hyoid bone in the plane of the future lingual septum. Its original position explains the attachment of a well-developed pyramidal lobe to the ventral surface of the hyoid bone. In its further development the thyroid mass moves more caudad and during the lengthening of the branchial region it is carried into its final position, caudal to the larynx. In extreme cases it may even extend into the mediastinum, and findings have been reported of a hernia of the thyroid gland into the thoracic cavity. In older persons, there may be a physiological thyreoptosis, since the larynx gradually assumes a

more caudal position, so that the thyroid is pushed toward the thoracic aperture. The thyroglossal duct lengthens out, of course, until finally it breaks up into small epithelial nodules, which normally disappear. The lateral lobes begin to expand further, numerous capillaries approach the surface of the epithelial tissue, penetrate into the interior and later break it up into numerous smaller groups and clusters of cells. These epithelial nodules finally hollow out, many of them not until after birth, and form closed follicles, in the lumen of which colloid begins to appear as early as the fourth month of fetal life. The mass of the lateral lobes is slightly increased by the addition of epithelial bodies, coming from the ventral portions of the fifth branchial clefts. These *ultimobranchial bodies* are taken into the area of the thyroid tissue, where they gradually disintegrate. Therefore they do *not* form any part of the thyroid gland (Grosser). The capsule of the gland is formed rather late in fetal life, so that tissues, foreign to the thyroid, may easily become enclosed within its area. This sometimes happens with the parathyroids IV; also muscle and ganglion cells have been found therein.

Variations.—All variations and abnormalities in the shape and size of the thyroid gland and the distribution of accessory thyroid nodules can easily be explained on an embryological and phylogenetic basis. The greatest range of variation is found in the pyramidal lobe and isthmus. Apparently, it is the phylogenetic tendency of the organ to lose its connection with the pharynx, push as far caudad as possible and then to spread out transversely, so as to form two distinct lateral lobes. Two symmetrical lobes are normal in some amphibians and birds. The most extreme variations in man would be, on the one hand, a well-developed, unpaired, pyramidal lobe, attached to the lingual septum or hyoid bone, with a well-formed isthmus (selachian and reptilian type); on the other hand, two lateral lobes entirely separated, or connected by a very thin isthmus, which may consist of connective tissue only. Between these two extremes all degrees of variations have been described. Sometimes one lobe may be very small, while the other is large. Remnants of the thyroglossal duct, sometimes *cranially* to the hyoid bone (27 per cent. of cases), may lead to the formation of small accessory thyroid nodules or, at least, epithelial cysts, lying between the fibers of the geniohyoid muscle. Such rudiments, in later life, may undergo a renewed development. Accessory thyroid glands, sometimes five or more, are more often formed from broken-off parts of the pyramidal lobe. All such nodules lie cranially to the gland proper. More distal portions of the gland may become cut off and then lie caudally to the larynx. A possible extension into the mediastinum and thorax has been mentioned above. The main gland may be absent entirely, while a number of smaller nodules assume its function. (In cyclostomes and teleosts we find scattered follicular units in place of a single encapsulated gland.) The connection with the foramen cecum may persist, or the latter may retain the form of a deep, branching canal, with mucous glands in its epithelium.

THE PARATHYROID GLANDS

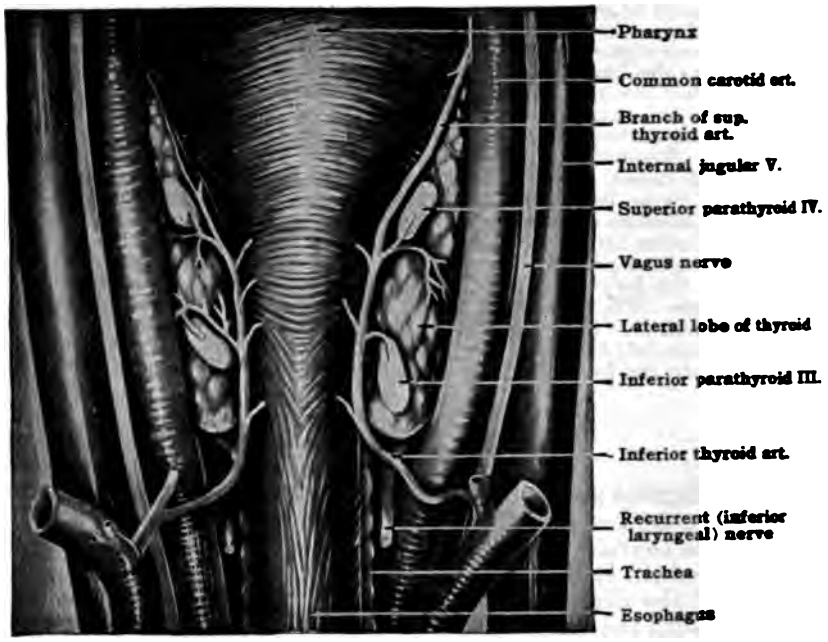
The **parathyroid glands** [glandulæ parathyroideæ] are small structures, usually two on each side, lying in the neighborhood of, or closely attached to, the dorsal surface of the thyroid gland. Not uncommonly, one may find one or the other nodule embedded in the thyroid tissue. Their structure is entirely different from that of the thyroid, as is also their physiology. Therefore they must *not* be grouped with the *accessory* thyroid glands. In spite of their minute size, they are of extreme importance, the removal of all the parathyroids leading usually to death.

The parathyroids are spherical or ovoid bodies, usually somewhat flattened (fig. 1057). Their *size* varies from 2 to 8 mm. in length. In old age they atrophy to some extent. Their *consistency* is firmer than that of the thyroid. Their *color* changes from a light pink in the young to a yellowish-gray in the old. They are easily mistaken for small lymph-nodules, or *vice versa*. Usually, they are situated on the dorsal surface of the lobes of the thyroid, sometimes near the medial border. Their position is rather variable; some may be found within the thyroid, or more caudally toward the sternum, attached to or enclosed in the thymus. The superior pair (parathyroids IV) lie on the finer branches of the inferior thyroid artery, usually dorsal to the recurrent nerve. They may be found as high up as the apices of the lateral lobes of the thyroid. The inferior pair (parathyroids III) lie near the base of the lateral lobes or still further caudal (see development). The average number of parathyroids is 4. It varies, however, from 1 to 12. A reduced number means either a fusion of two or more anlages, misplacement of one or the other bud, or a retrogression (retarded differentiation and ultimate absorption) of some rudiments. Such a process is normal in some mammals. A number higher than 4 would mean a splitting of some of the rudiments into secondary nodules.

The **blood-supply** of the parathyroids (fig. 1057) goes through branches of the inferior (sometimes superior) thyroid arteries and veins, each nodule receiving its artery, which enters at the hilus, a slight depression of the connective tissue capsule. The **lymph-vessels**, in all probability, also belong to the thyroid system. The **nerves** (sympathetic) likewise come from the thyroid branches.

Development.—The parathyroids develop from the epithelium of the dorsal, cranial areas of the most lateral extremities of the third and fourth gill clefts (fig. 41). They are entirely of entodermal origin. These epithelial bodies are soon approached by blood-vessels, which break up the cellular mass into a system of irregularly arranged clusters nd cords of cells, between which the vessels form a complicated system of sinusoidal channels. The epithelial anlages soon lose connection with the branchial epithelium and begin their migration in a caudal direction. The pair coming from the third clefts differs somewhat in its behavior from that coming from the fourth. The parathyroids IV usually form the upper pair of glands, while the parathyroids III travel farther toward the sternal region. The glands IV usually become attached to, sometimes (rarely in man) embedded within, the thyroid. This variation, of course, depends on the time of formation of the capsule of the thyroid gland, and also on the lateral extension of the thyroid band (see development of thyroid), as the latter travels toward the cricoid region. The glands III, on the other hand, may retain their connection with the thymus-anlages, and may then travel as far as the mediastinum, and remain attached to, or,

FIG. 1057.—PARATHYROID GLANDS, VIEWED FROM BEHIND (NATURAL SIZE).



more often, embedded within the thymus. This connection is a very short strip of branchial epithelium and can often be seen even in older embryos; the thymus buds, as it were, pulling along the parathyroids III. Should this connection be broken very early, the parathyroids III may fail to migrate at all, and may then be found in a rather cranial location, even more so than the thyroid.

THYMUS

The thymus gland is distinctly a double organ, so it is perhaps more correct to speak of the right and left thymus instead of its right and left lobes. The two lobes, however, are so closely attached to each other by connective tissue—rarely they are connected by a true isthmus—that usually the thymus has been described as a single, unpaired organ. Its development and the distinct separation into two bodies at the cranial end speak for its duplex anatomical structure.

The shape of the thymus is hard to define, since the gland on account of its very soft consistency easily molds itself to the surrounding structures. It might best be described as a pyramid, the broad base occupying the thoracal end, while the apices are represented by the thinned-out, cervical portions. The dorsoventral diameter is certainly greater than appears in the dissecting room, where the gland often is found to be rather flat. The right lobe usually overlaps the left one.

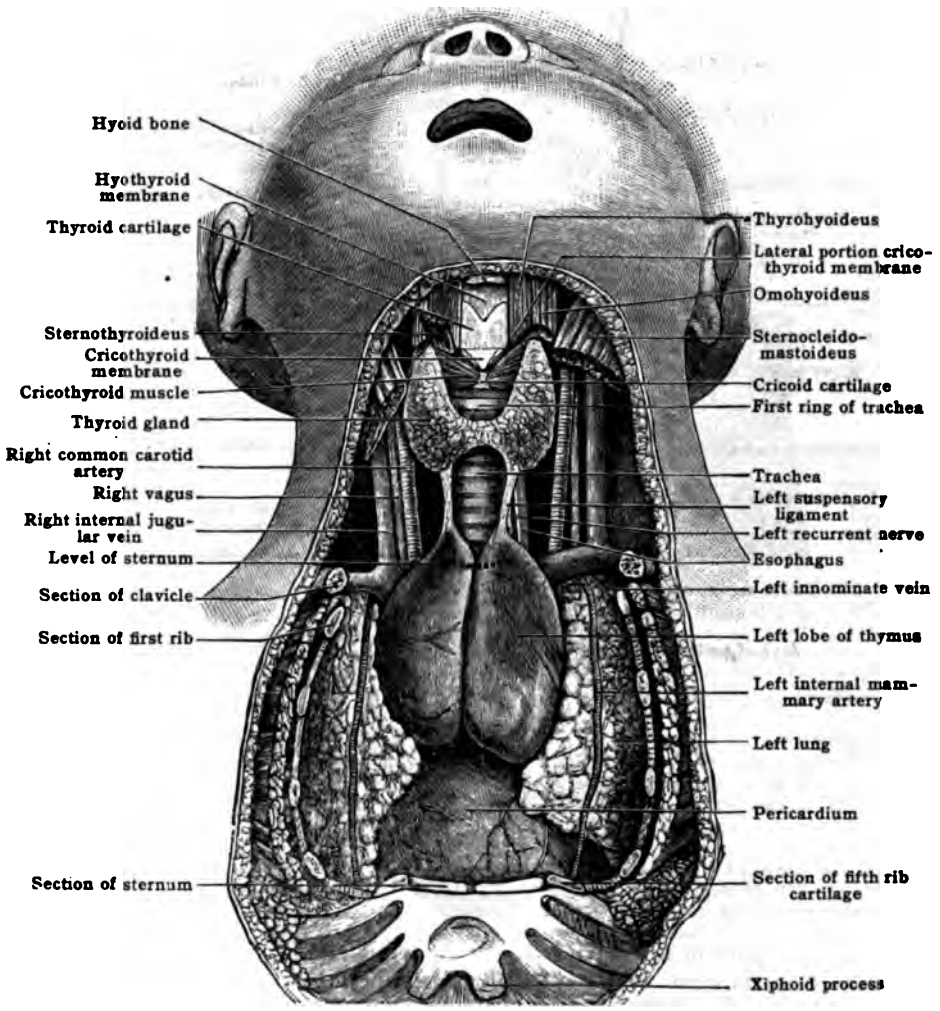
Size.—The thymus is relatively largest in the child (figs. 1058, 1059) and reaches its absolute maximum of development in the adolescent. Soon after puberty it undergoes a retrogression or involution, the thymic tissue gradually being replaced by fat, so that in the dissecting room one rarely finds a true glandular body, but a lobe of adipose tissue in its stead. The shape of the epithelial organ, previous to involution, may approximately be retained, and its replacement

by fat proceeds by no means as fast and to such a degree as was commonly believed. Even in older individuals, thymus parenchymal tissue is still present.

The *length* of the organ in the newborn is variously given from 4 to 6 cm., the width from 1.2 to 4 cm., the thickness from 0.8 to 1.4 cm. More instructive are the *weight* measurements (quoted from Sobotta, after Hammar): newborn, 13.26 g.; 11–15 years, 37.52 g.; 16–20 years, 25.28 g.; 46–55 years, 12.85 g. The greatest weight is, therefore, reached during the adolescent period. In the female, the gland is somewhat lighter than in the male. Still more interesting is the weight of the parenchyma, calculated by Hammar after the exclusion of the adipose and connective tissue: newborn, 12.33 g.; 11–15 years, 25.18 g.; 16–20 years, 12.71 g.; 46–55 years, 1.48 g. Thus the largest amount of glandular tissue is also present at puberty. In disease or malnutrition the thymus readily retrogresses (premature involution).

While it is definitely established that (1) the thymus is a gland of the infantile period (group *a*, see p. 1311); (2) the normal physiology of the thymus is upset by an abnormal progress in

FIG. 1058.—THYMUS AND THYROID GLAND IN A CHILD AT BIRTH.



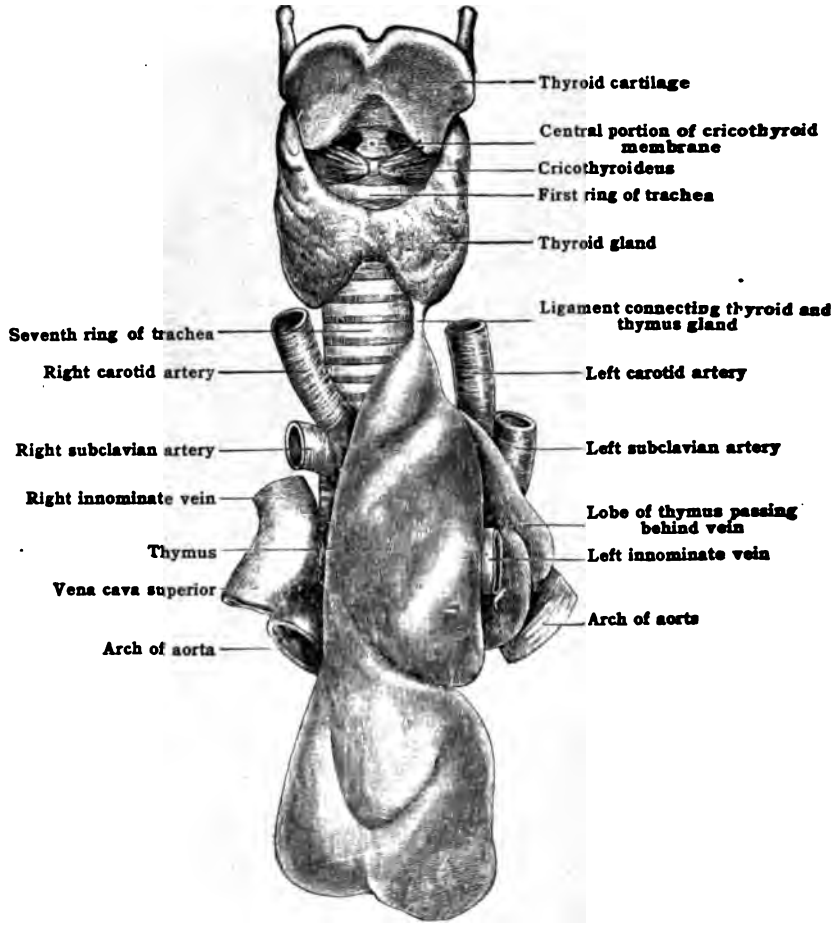
growth and differentiation (precocious involution, delayed involution); (3) the thymus most readily responds to any faulty stimulus exerted by any of the other glands of group *a*, whether hyper- or hypoplastic; yet it is by no means certain whether the thymus is able to act as a *primary, causal* factor in this physiological ring of developmental glands (group *a*), or is simply *secondarily* influenced and controlled by the other members. In other words, a primary internal secretion of the thymus might, perhaps, be questioned. However, there can be no doubt, physiologically, that a reciprocity exists between the condition of the thymus and the state of differentiation of an organism. Anatomically, on the other hand, we must admit that the morphological basis for a secretion is wanting.

The **color** of the thymus changes from a pink or reddish tint in the fetus to a pale reddish-gray in the growing child. Later it assumes the yellowish color of fat. It is surrounded by a fine, but firm, connective tissue **capsule**, sending trabeculæ into the body and dividing the latter into numerous small lobules [lobuli thymi] the outlines of which can be seen and felt on the surface. By looser connective tissue it is attached to the neighboring structures, more so on its dorsal than on its ventral aspect.

Topography.—The greater portion of the thymus lies in the upper anterior mediastinal space (thoracic portion); the cranial extremities of the two lobes, when well developed, extend into the cervical region (cervical portion) (figs. 1058–1060).

The *cervical portion* of the thymus lies ventral to the trachea, in the thoracal aperture and lower cervical region, starting at about the sixth cervical vertebra. It is covered by the superficial and deep layers of the cervical fascia and the sternothyroid and sternohyoid muscles. It is usually surrounded by some adipose tissue of the suprasternal region. It may be connected to the thyroid on each side by a ligament or strand of fibrous connective tissue (figs. 1058, 1059).

FIG. 1059.—THYMUS IN A CHILD OF TWO YEARS.



The *thoracic portion* lies in the upper, anterior mediastinal space between the two mediastinal laminæ of the pleura. The median portion of its somewhat convex, ventral surface rests against the dorsal aspects of the sternum and neighboring costal cartilages (to the fourth). An excessively large thymus may reach to the diaphragm. In the more cranial region of the manubrium, the sternohyoid and sternothyroid muscles intervene between the sternum and the thymus. The more caudal portion of the concave, dorsal surface of the gland is closely applied to the pericardium. The cranial portion of the dorsal surface rests against the large vessels, aortic arch, innominate artery and veins, common carotids, etc. Occasionally, the left innominate vein may lie on the ventral side. As the individual grows, the thymus is withdrawn more and more from the prepericardial mediastinal space and finally occupies only its upper region.

Blood-vessels.—The arteries of the thymus are branches of the subclavian, or of the internal mammary artery, either directly or springing from the anterior mediastinal branches. The cranial portions may be supplied by branches of the inferior or median thyroid (ima) arteries.

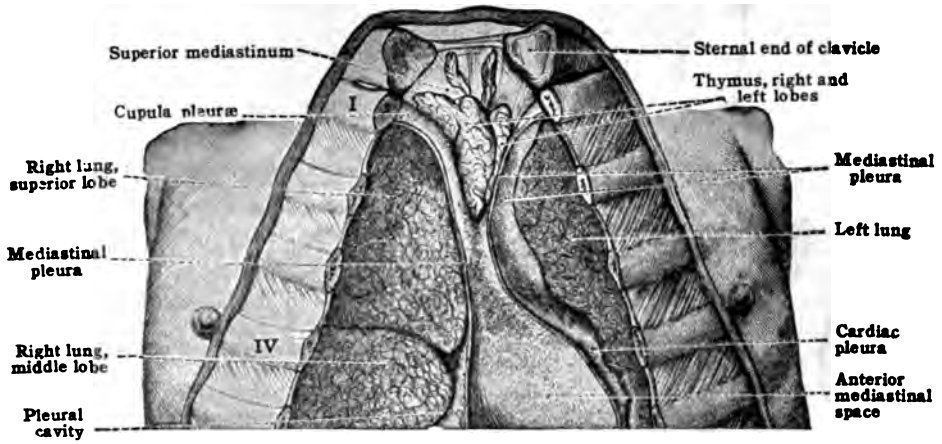
The numerous veins of the thymus drain into the left innominate vein (fig. 564), some into the internal mammary veins and their tributaries or the inferior thyroid veins.

Lymph-vessels.—The exact distribution of the rather scanty lymph-vessels around and within the thymus has still to be investigated, although definite channels have been demonstrated within the connective tissue trabeculæ and parenchyma. The drainage of the large lymph-channels probably proceeds into the anterior mediastinal lymph nodes.

Nerves.—Fine, non-medullated nerve-fibers have been demonstrated within the gland, forming networks around the vessels and in the trabeculæ. They probably belong to the sympathetic system. Fibers from the vagus have also been mentioned.

Development.—The thymus bodies arise (see p. 56) during the fourth week of fetal life (5–7 mm. embryos) from the ventral region of the most lateral extremities of the third, sometimes also of the fourth, gill clefts (fig. 41). In man, the thymus is entirely of entodermal origin. The thymus diverticulum, sometimes distinctly hollow, grows in a ventral and caudal direction and lengthens out into a solid mass of epithelial cells, which loses its connection with the pharyngeal epithelium (at about 12 mm.). Blood-vessels very soon approach its surface and penetrate into the interior. No connection is established with the lobe of the other side. Later, when the two portions move still more caudad into the sternothoracal space, and after a connective tissue capsule has been formed, the two glands lie close against each other, the right one usually in a more ventral position and overlapping the left. If an epithelial body is formed from the fourth gill cleft, it may undergo an independent development. Usually, it is taken up into the

FIG. 1060.—THYMUS IN AN ADULT. ×13. (From Toldt's Atlas.)



main thymic tissue and there retrogresses; or it may form an additional lobe. The parathyroids, which develop from the same gill clefts as the thymus bodies III and IV, may be attached to or enclosed in the thymus-tissue. As the epithelial thymus mass moves caudad, its cranial portion (stalk) disintegrates. The glandular tissue then sprouts out in the form of small lobules. For some time a distinct central tract or possibly even a hollow canal is noticeable.

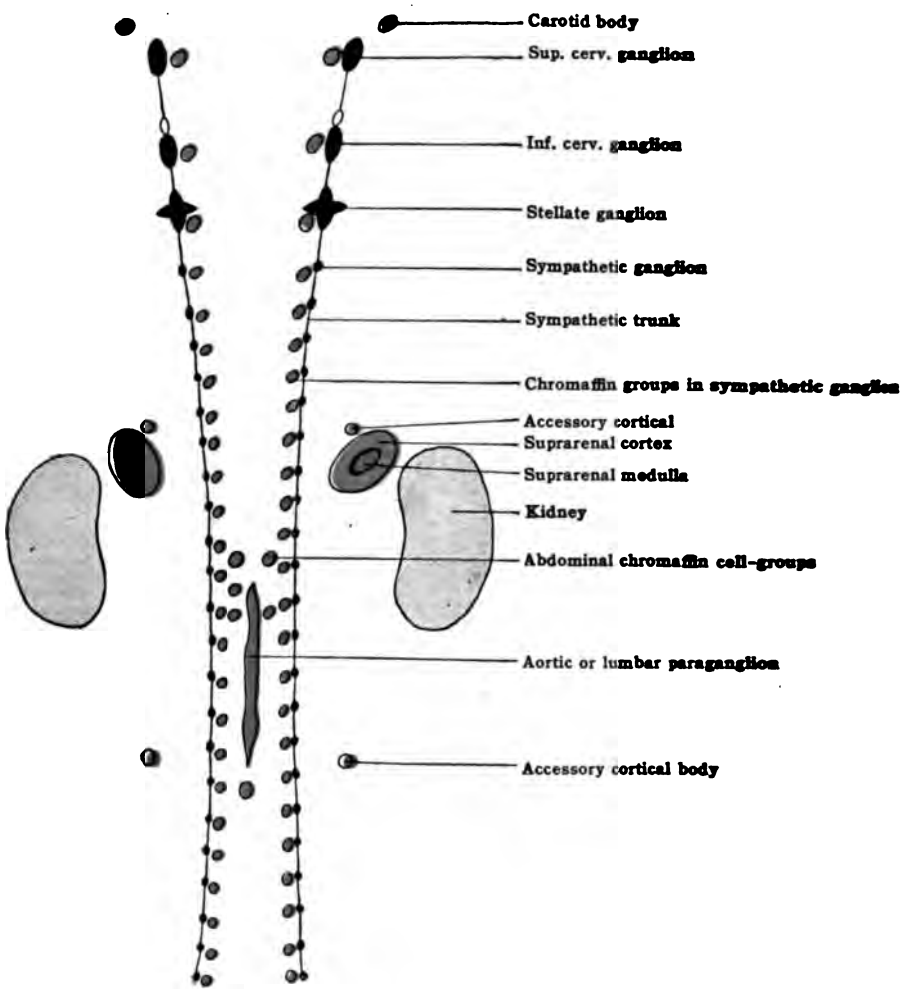
Variations.—Variations from the anatomical norm are usually due to some irregularity in development. Like the thyroid, the thymus seems to have a phylogenetic tendency to move toward the thoracic region. A failure to do so or a failure to reduce the stalk will give a large cervical thymus (reptilian or avian type), sometimes bordering on the thyroid. At times, the cervical portion is represented merely by a strand of connective tissue. Accessory thymus glands may be broken-off portions of the stalk, left behind in the caudal migration of the tissue, or may come directly (in rare cases) from the epithelium of the clefts. In lower forms, several (2–5) branchial clefts assist in the formation of the organ. In monsters (hemicephalic, for instance) the thymus may be absent. An abnormally long persisting thymus is found in the pathological condition of *status lymphaticus* or status thymicus. Also in cases of sudden death in children (thymic death) a large thymus has been found.

THE CHROMAFFIN SYSTEM

To the **chromaffin system** (fig. 1061) belong a number of organs, some minute in size, which are serially arranged along both sides of the dorsal aorta, most of them in close proximity to the sympathetic ganglia. They are mainly made up of chromaffin cells, the term 'chromaffin' designating a special chemical affinity of these cells for certain salts of chromic acid. The cells are derived from cell groups, the greater portion of which is used up in the formation of the sympathetic ganglia. Originally, the sympathochromaffin cells are a part of the ganglionic crest, which, shortly after closure of the neural canal, is constricted off to form the spinal and sympathetic ganglia. The chromaffin cells are, therefore, ectodermal (neural plate) cells, which, by way of the ganglionic bodies, have traveled a

further distance to form the chromaffin or paraganglionic bodies. Due to their place of origin, it is not unusual to find true ganglionic cells in these bodies. To the chain of these paraganglionic bodies belong: the **carotid bodies**; the **paraganglia proper**, the **aortic bodies**; and, in part, the **suprarenal glands**, the medulla of the latter being a pair of larger and further developed **paraganglia**. The chromaffin cells are *not* specialized sympathetic ganglion cells, but present a separate type of cell, which can be recognized as such rather early in development.

FIG. 1061.—DIAGRAM SHOWING THE CONSTITUENTS OF THE CHROMAFFIN SYSTEM IN MAMMALS. Chromaffin structures in red; cortical in blue. (Swale Vincent, 'Internal Secretion and the Ductless Glands.' Edward Arnold, London, 1912.)



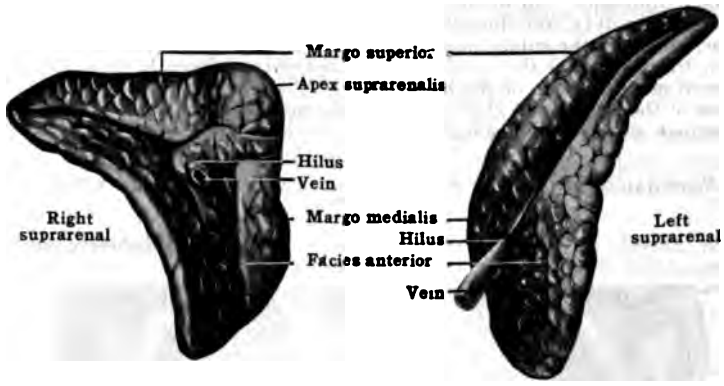
THE SUPRARENAL GLANDS

The **suprarenal gland** [glandula suprarenalis] (adrenal gland) lies near the cranial pole of each kidney, close to that body, so that the convex surface of the kidney causes a concave impression on the suprarenal (fig. 1064). The left gland lies more along the anteromedial border of the kidney, reaching at times as far down as the hilus and touching the renal vessels. Considering the concave surface as the *base*, the suprarenal gland might be described as a very low pyramid, the basal surface resting against the kidney, the *apex* pointing toward the diaphragm (figs. 1062, 1063). Sometimes the pyramid is flattened down to almost a semilunar plate, its convex surface facing craniomedially. This is especially true for the left suprarenal. Each gland has an anterior, a posterior and a basal surface. Superior and medial borders are distinguished, and the left suprarenal also presents a left border. On the anterior surface, there is a slight

groove noticeable, the *hilus*, where the central vein appears on the surface (fig. 1062). The gland is enclosed in its tough, connective tissue *capsule* and is embedded in adipose tissue. It is surrounded by the renal fascia (fig. 1098) and is more firmly attached to the latter than to the kidney.

The weight of the gland is given from 4 to 18 grams, undoubtedly liable to considerable physiological variation. The measurements vary from 40 to 60 mm. in length and 20 to 30 mm.

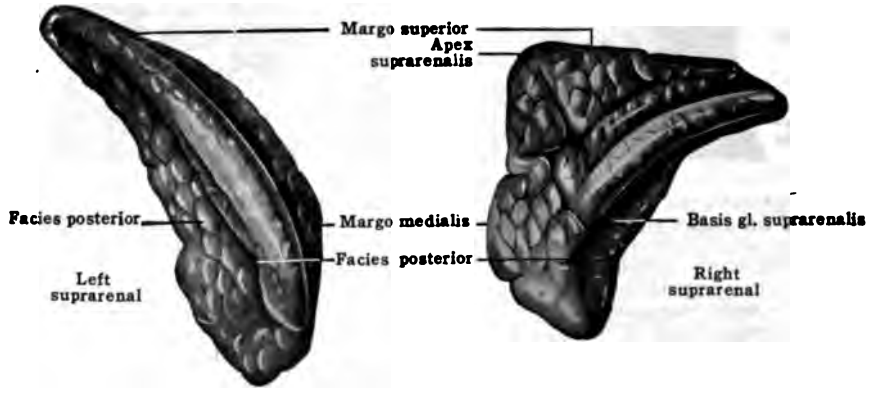
FIG. 1062.—THE SUPRARENAL GLANDS, VENTRAL VIEW.



in width. The gland is relatively large in the fetus and in the young. In malformations (anencephalic monsters, for instance), it is considerably enlarged. Its color is of a yellow or brownish tint. Its texture is rather firm.

Topography.—The suprarenal glands lie in the epigastric region (figs. 965, 1018, 1064), at about the level of the eleventh thoracic vertebra. The posterior surface rests against the lumbar area of the diaphragm. The anterior surface of the right gland touches the inferior vena cava medially, the liver laterally and (sometimes) the duodenum below. The left gland lies somewhat more cranially

FIG. 1063.—THE SUPRARENAL GLANDS, DORSAL VIEW.



and nearer the aorta, behind the lesser omental sac. Anteriorly it is in relation with the posterior surface of the stomach above, the posterior surface of the pancreas and the splenic vessels below, and (often) the renal surface of the spleen laterally.

Structure.— From the fibrous capsule, numerous trabeculæ are given off which pervade the gland and form septa between the groups and rows of cells. Within the capsule, the suprarenal is composed of two distinct portions, an external firmer, yellowish layer, the *cortex* [substantia corticalis], and an internal, softer layer, the *medulla* [substantia medullaris], which usually appears dark reddish-brown in color, on account of its large blood content. These two portions, the cortex and medulla, really represent two distinct glands which are different both physiologically and morphologically (see further under Development and Variations).

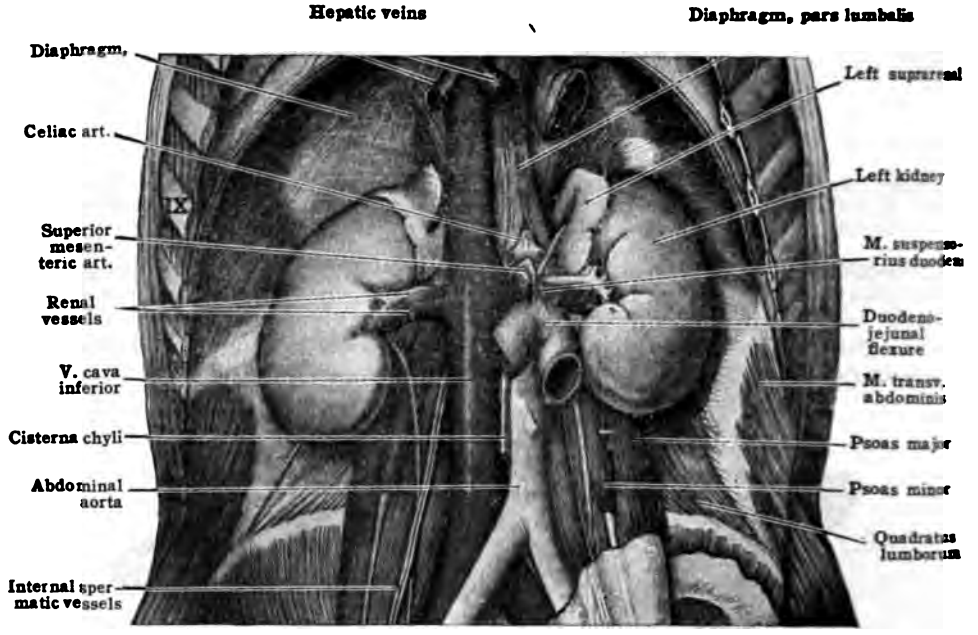
Blood-supply.—The blood-supply of the suprarenal gland is unusually abundant. Three arteries, the superior, the middle and the inferior suprarenal artery, approach the capsule and

penetrate into the interior. They are branches of the inferior diaphragmatic artery, aorta and renal artery respectively (fig. 570). All veins collect into one large **central vein**, lying in the medulla of the organ and passing out at the hilus as the **suprarenal vein**, which, on the right side, drains into the inferior vena cava, on the left side into the renal vein. Some arterial twigs form a network in the capsule, and special veins drain that area as tributaries to the inferior diaphragmatic veins, or veins of the adipose and fibrous capsule of the kidney.

The **lymph-vessels** of the suprarenal form a plexus directly under the capsule and a second one in the medulla. The peripheral plexus drains into vessels leaving the capsule; the central one into those following the central and suprarenal vein. On the right side, the lymph-channels connect ventrally with 2 or 3 lymphatic nodules near the aorta; and dorsally with a node near the crus of the diaphragm. On the left they drain ventrally into a node situated at the point of origin of the renal artery, and dorsally also into a node between the aorta and the crus of the diaphragm, or, following the splanchnic nerve through the diaphragm, into a mediastinal node lying between the aorta and the ninth thoracic vertebra. Some lymph-channels also drain into the subperitoneal network of the kidneys.

The **nerves** of the suprarenal gland, forming the **suprarenal plexus**, connect with the renal and celiac plexuses and the celiac ganglia.

FIG. 1064.—VENTRAL VIEW OF THE SUPRARENAL GLANDS, IN SITU. × ⅓. (From Toldt's Atlas.)



Development.—In the discussion of the development of the suprarenal gland, the two portions of the gland, cortex and medulla, have to be considered separately. It is the medullary portion which is derived from the ectodermal cells of the ganglionic crest, and which alone contains chromaffin (phæochrom) cells. Very early, such cells are split off from the nodules containing the sympathetic ganglion-cells, and migrate further ventrad, so as to lie lateroventrally to the aorta (paraganglia). Several such nodules, near the cranial end of the gonad, combine into a larger mass of cells, lying between the dorsal aorta and the dorsomedial border of the mesonephros. They come into close approximation to the group of mesoderm cells derived (at least the greater part) from that narrow strip of mesothelium of the body cavity between the dorsal mesentery and the genital ridge. There is, in embryos of 6 mm., an actual budding of mesothelial cells into the underlying mesenchyma, sometimes in tubular form, as occurs in pig embryos. These rapidly multiplying cells soon lose their connection with the mesothelium and attempt to form a complete layer of mesoderm cells around the ectoderm cells, derived from the sympathetic ganglia. In this way, the mass of the chromaffin cells, the medulla, is finally enclosed within the outer cortical layer. Comparatively large twigs of the dorsal aorta (mesonephric vessels) are seen to approach this mass very early. The fibrous capsule is formed rather late. For further details on the growth of the suprarenal glands, see DEVELOPMENTAL ANATOMY, p. 56.

Variations.—In lower forms, most of the anamnia, the two portions of the suprarenal glands are still separate as *interrenals* (cortical substance) and *adrenals* (medullary substance). In reptiles, the partial union of the two structures begins to appear. Therefore, it is not at all unusual, even in man, to find, in addition to the suprarenal glands proper, some accessory structures, made up of one or the other, or of both components. Only such nodules, which consist of cortex and medulla, are properly called **accessory suprarenal glands**. They are usually found near the cranial region of the kidneys, sometimes embedded in the cortex of the kidney or in the suprarenal itself. More often, one finds nodules made up of cortical tissue

only. These *accessory cortical* bodies have been found in more caudal regions of the abdominal cavity, and since, during development, the cortical (mesothelial tissue) is situated close to the germinal epithelium, such nodules may, with the descent of the gonad, be carried into the pelvis or even the scrotum. Such nodules, lying in the adventitia or the ligaments of the genital glands, the spermatic cord or the broad ligament of the uterus, at times have been the cause of a wrong diagnosis of true hermaphroditism, since they were mistaken for rudiments of the genital glands of the opposite sex. Still more often one finds, even in the pelvic region, scattered masses of the medullary substance, which are, however, *not* accessory suprarenals, but misplaced paraganglia. A complete absence of the suprarenal glands is rare and then only in cases of severe malformations. A hypoplastic condition is often found in connection with hypoplasia of the genital glands, and hyperplasia of the thymus and lymphatic structures (*status thymolymphaticus*).

THE CAROTID BODY

The **carotid body** [glomus caroticum] is a small, oval nodule, approximately 2 by 7 mm. in size, of paraganglionic (chromaffin) tissue, usually lying on the medial side of each common carotid artery, at or in the neighborhood of its branch-

FIG. 1065.—THE GLOMUS CAROTICUM (CAROTID BODY). (From Testut, after Princeteau.) 1, Carotid body; 2, 3, 4, common, external and internal carotids; 5, int. jugular; 7, inf. cervical sympathetic ganglion; 8, vagus.

ing into the external and internal carotids (fig. 1065). The connective tissue of the adventitia of these vessels adds to the formation of the capsule, from which elements penetrate into the interior of the nodule. Thus, the carotid body is rather closely attached to, and sometimes even partially embedded in, the tunica externa of the arteries.

It is richly supplied by fine *blood-vessels*. The arteries arise from the carotids, and the venules drain into the internal jugular vein or its tributaries. The *nerve-supply* is mainly sympathetic, coming from the inferior cervical ganglia. Branches have been described from the vagus and laryngeal nerve. The carotid body may consist of several small nodules, embedded in adipose tissue.

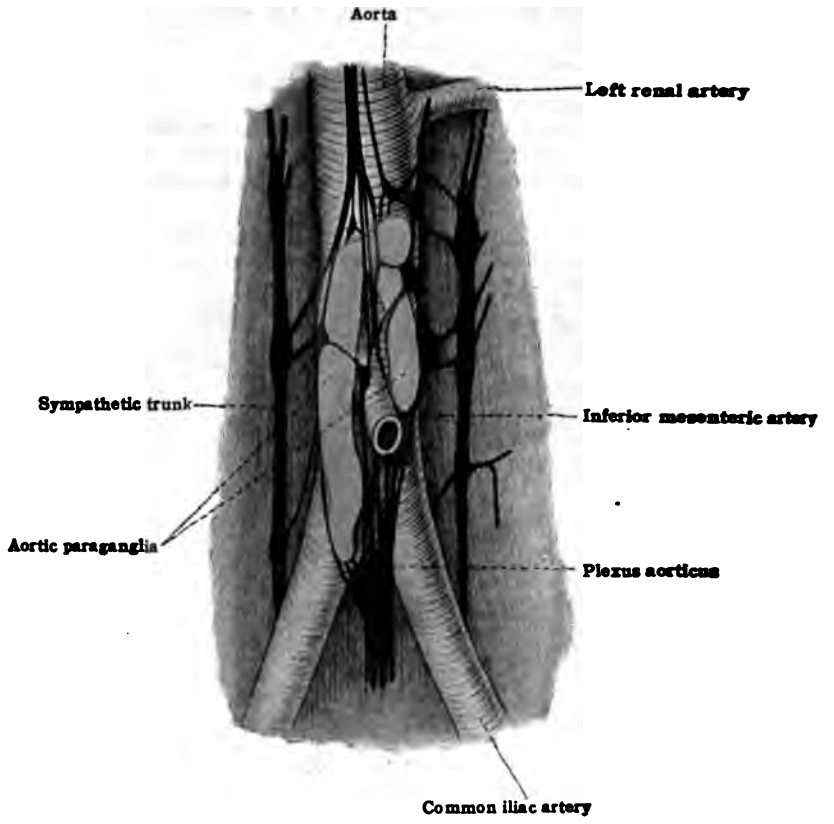
THE AORTIC PARAGANGLIA

The **paraganglia** proper are minute accumulations of chromaffin cells, lying inside or attached to the capsule of the ganglia of the sympathetic chain and of all the abdominal sympathetic plexuses.

The **aortic** or **lumbar paraganglia** (paraganglia lumbalia) represent a special group of chromaffin bodies, which develop from the sympathetic nodules and are, therefore, of ectodermal origin. While the rest of the chromaffin bodies are very small nodules, the carotid bodies being the largest of them, the right and left aortic, or abdominal paraganglia, attain a larger size. They may represent a fusion of several large chromaffin bodies into elongated, cylindrical masses, lying behind the peritoneum, ventrolaterally to the dorsal aorta, at about the level of

the origin of the inferior mesenteric artery (fig. 1066). Their size and extension is extremely variable. They may consist of a number of smaller nodules (as many as 70 have been counted). Often the right and left bodies are connected with each other. Their sympathetic nerve-supply comes from the abdominal aortic plexus. They are said to undergo retrogression after puberty.

FIG. 1066.—AORTIC PARAGANGLIA. (Zuckerkandl.)



THE HYPOPHYSIS

The **hypophysis cerebri** (pituitary gland) is an ovoid, somewhat flattened mass attached to the end of the infundibulum. The latter is an attenuated, funnel-shaped process of the tuber cinereum (see p. 832), which extends downward and forward (fig. 1068). The cavity of the infundibulum (infundibular recess) is a continuation of the cavity of the tuber cinereum and a part of the third ventricle; it may extend almost to the hypophysis (fig. 1067).

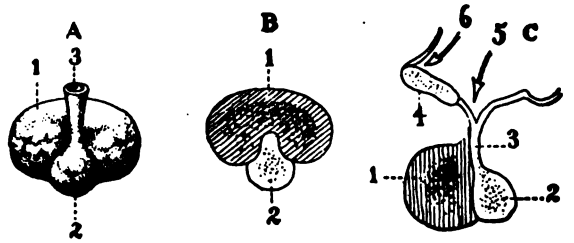
The hypophysis is lodged in the sella turcica of the sphenoid bone, where it is held down and roofed in by a fold of the inner layer of the dura mater, the *diaphragma sellæ*. It is surrounded by a dense, fibrous capsule and consists of two lobes, the larger *anterior*, glandular or buccal, lobe, possessing a concave posterior surface; and the smaller *posterior* or neural lobe, which is the terminal swelling of the infundibulum. Usually, the neural portion fits into the concavity of the glandular portion (hypophysis proper) as a ball into the hollow of the hand (fig. 1067, B). It is supplied by the *hypophyseal branches* of the internal carotid artery.

Development.—The entire body is of ectodermal origin, the anterior lobe arising from the ectoderm of the primitive oral cavity (3 mm. embryo), the posterior from the ectoderm of the neural tube. The posterior lobe develops as a ventral diverticulum of the diencephalon (see p. 56). Through the infundibulum, it retains its connection with the tuber cinereum. The anterior lobe develops as a dorsal diverticulum from the roof of the stomodeum (Rathke's pouch) and very soon (second month) loses its connection with the oral ectoderm. It then forms a closed vesicle. Remnants of its duct through the later sphenoid bone can be seen for some time and

may give rise to accessory glandular nodules, or cysts and tumors. It is claimed that at least one accessory nodule is often found forming the *pharyngeal hypophysis*. A persistent canal is occasionally found in the sphenoid bone (fig. 1069). In myxinoids and sharks, the duct into the oral cavity remains patent. Even in man, the adult hypophysis possesses a cavity, the rudiment derived from the embryonic buccal cavity.

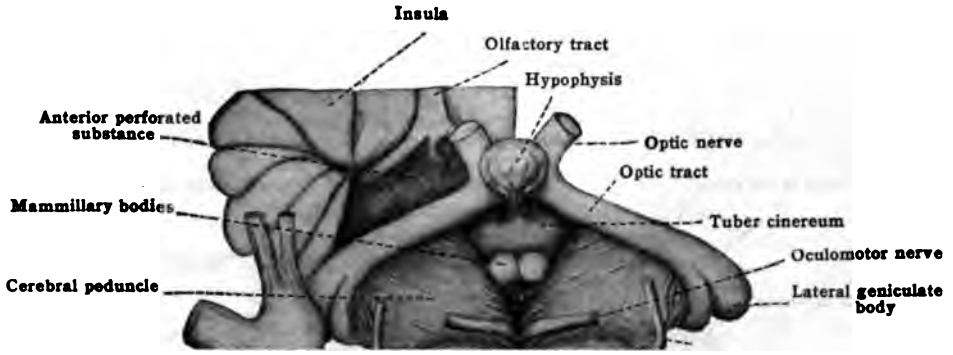
The structure of the anterior lobe of the gland is that of a typical organ of internal secretion. Its influence upon growth, differentiation and metabolism is well established. In cases of excessive growth of the skeleton (gigantism) and connective tissue (acromegaly) and late epiphyseal ossification (status thymicus), as well as in hypoplasia of the sex-glands, the anterior

FIG. 1067.—DIAGRAMS OF THE HYPOPHYSIS CEREBRI. (After Testut.) A, posterior view, B, frontal section; C, sagittal section. 1, anterior lobe; 2, posterior lobe; 3, infundibulum, 4; optic chiasma; 5, infundibular recess of 3d. ventricle; 6, optic recess. The infundibulum in C is somewhat too short.



lobe of the hypophysis is found to be enlarged or diseased. After removal of the thyroid gland a vicarious hypertrophy of the glandular lobe, with attempt of colloid-formation, may set in During menstruation, and still more during pregnancy, a normal temporary hyperplasia of this lobe is noticeable, sometimes to such an extent, that pressure may be exerted on the neighboring optic chiasma and temporary blindness may follow. That the neural portion plays an important rôle in metabolism (urinary excretion, sugar, etc.) is claimed by some physiologists. Anatomically, however, no basis for any secretion can be detected, except in the so-called *intermediate portion*, a part of the glandular lobe, lying between it and the neural lobe. For further details on topography and clinical relations, see p. 1342.

FIG. 1068.—HYPOPHYSIS AND RELATIONS. Inferior view.



THE PINEAL BODY

The **pineal body** [corpus pineale] or **epiphysis,** a part of the epithalamus, is a nodular or cone-shaped structure, lying in the transverse cerebral fissure, below the splenium corpus callosi, and extending in a caudal direction from the roof of the posterior extremity of the third ventricle (figs. 675, 706, 1070). It is connected to the medial surfaces of the optic thalami by two attenuated strips, the habenulæ. Its stem is attached just above the posterior commissure of the cerebrum, and its body rests in the groove between the superior quadrigeminate bodies (fig. 1071). The pineal body is covered by pia mater and is involved in a continuation of the tela choroidea of the third ventricle. It is surrounded by a dense capsule of fibrous tissue and consists of groups of epithelioid cells derived from the ependymal layer of the ventricle. Between these cells are frequently found accretions (brain-sand), consisting of mixed phosphates of calcium, magnesium, and ammonium, and of calcium carbonate, surrounding organic particles.

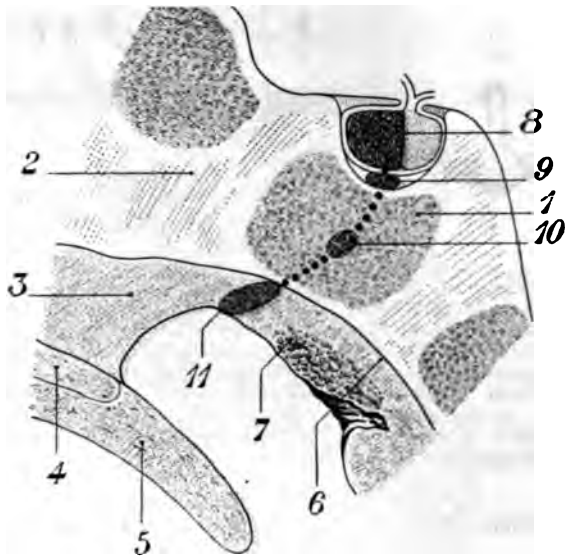


FIG. 1070.—PINEAL BODY AND RELATIONS. Superior view.

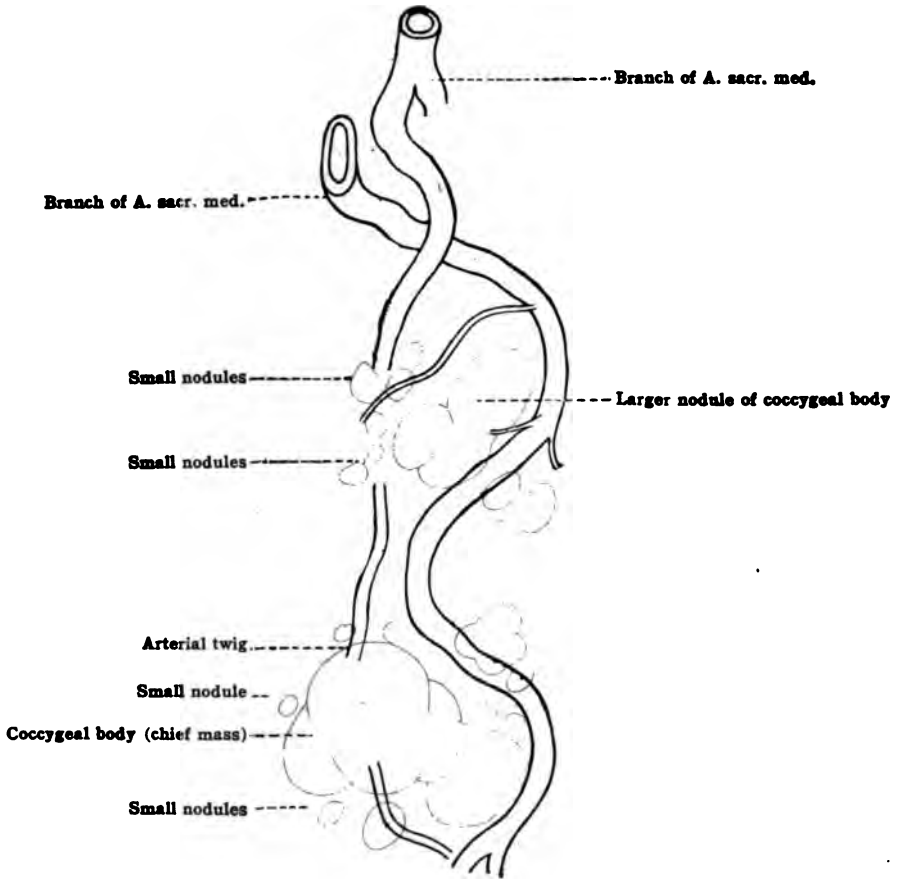
COCCYGEAL BODY

Ventral to the tip of the coccyx, between the tendons of the anterior sacro-coccygeal muscles, along the median sacral artery are one or more small, varicose nodules (usually there are several accessory nodules), called the **coccygeal body** [glomus coccygeum] (fig. 1071). It is apparently *not* a glandular organ and has nothing to do with the chromaffin system. However, its nature is entirely doubtful. The afferent artery forms a skein of anastomosing vessels, which drain into the median sacral vein. Around the endothelial tubes of the vessels, several layers of spheroidal cells are found, presenting the appearance of epithelioid cells.

FIG. 1071.—DIAGRAM SHOWING RELATIONS OF THE COCCYGEAL BODY AND ACCESSORY NODULES TO THE MIDDLE SACRAL ARTERY. (J. W. Thomson Walker.)



They are considered to be modified muscle-cells. Between these cell groups are found connective tissue and smooth muscle-fibers. It marks the termination of the median sacral artery, and thus takes the place of the rudimentary caudal vessel.

SECTION XIV

CLINICAL AND TOPOGRAPHICAL ANATOMY

REVISED FOR THE SIXTH EDITION

BY DEAN LEWIS, M.D.

PROFESSOR OF SURGERY, RUSH MEDICAL COLLEGE, CHICAGO, ILLINOIS

IN describing the clinical and topographical relations, the divisions of the body will be successively considered in the following order: head, neck, thorax, abdomen, pelvis, back, upper and lower extremities. For further details concerning the structure and relations of the various organs, the reader should consult the preceding sections devoted to the corresponding systems.

THE HEAD

The bony landmarks of the head will first be considered, followed by a separate description of the cranium and the face.

Bony landmarks.—These should be studied with the aid of a skull, as well as on the living subject. Beginning in front is the **nasion,** a depression at the root of the nose, and immediately above it, the **glabella,** a slight prominence joining the two **superciliary arches.** These points mark the remains of the frontal suture, and the junction of the frontal, nasal, and superior maxillary bones and one of the sites of a meningocele. In the middle line, behind, is the external occipital protuberance, or **inion,** the thickest part of the vault, and corresponding internally with the meeting-point of six sinuses. A midline joining the inion and glabella corresponds to the sagittal, and occasionally the frontal, suture, the falx cerebri, the superior sagittal sinus, and the longitudinal fissure of the brain. From the inion the **superior nuchal lines** pass laterally toward the upper and back part of the base of the **mastoid processes,** and indicate the first or so-called horizontal part of the transverse (lateral) sinus (fig. 1078).

The **transverse sinus** usually presents a varying curve upward and runs in the tentorium. The second or sigmoid portion turns downward on the inner surface of the mastoid, then forward, and lastly downward again to the jugular foramen, thus describing the double curve from which this part takes its name. In the jugular foramen the vessel occupies the posterior compartment; its junction with the internal jugular is dilated and forms the bulb. A line curved downward and forward from the upper and back part of the base of the mastoid, reaching two-thirds of the way down toward the apex, will indicate the second part of the sinus. The spot where it finally curves inward to the bulb would be about 1.8 cm. (¾ in.) below and behind the meatus. The two portions of the transverse sinus meet at the asterion laterally; at the entry of the superior petrosal sinus medially. The right transverse sinus, the larger, is usually a continuation of the superior sagittal sinus, and, therefore, receives blood chiefly from the cerebral cortex; the left, arising in the straight sinus, drains the interior of the cerebrum and the basal ganglia. Each transverse sinus receives blood from the temporal lobe, the cerebellum, diploë, tympanic antrum, internal ear, and two emissary veins, the mastoid and posterior condylar.

About 6.2 cm. (2½ in.) above the external occipital protuberance is the **lambda,** or meeting of the sagittal and lambdoidal sutures (posterior fontanelle, small and triradiate in shape). It is useful to remember, as guides on the scalp to the above two important points, that the lambda is on a level with the superciliary ridges, and the external occipital protuberance on one with the zygomatic arches.

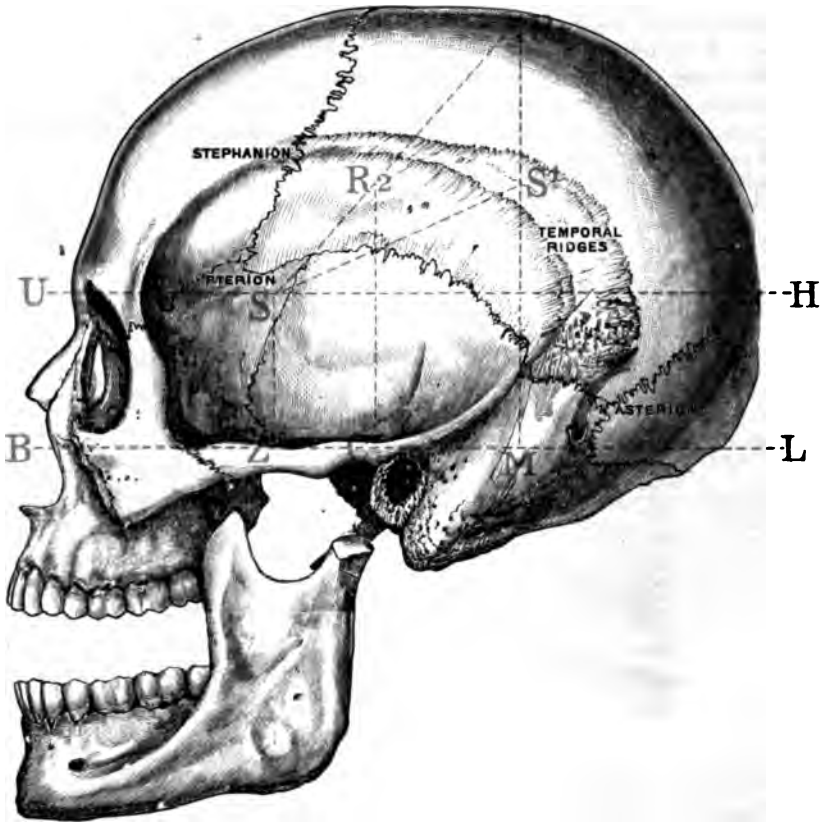
Below the external occipital protuberance, between it and the foramen magnum, an **occipital,** the commonest form of cranial **meningoceles,** makes its appearance. It comes through the median fissure in the cartilaginous part of the squamous portion of the bone.

further, corresponds to the anterior lateral fontanelle. On the side the **zygomatic arch,** the **temporal ridge,** and **external auditory meatus** tion. That important landmark, the **zygomatic arch,** wide in front formed by the zygomatic (malar), narrowing behind where it joins th gives off here three roots, the most anterior marked by the eminentia in front of the mandibular (glenoid) fossa, the middle behind this join posterior curves upward and backward to be continuous with the tem Within the zygomatic arch lie **two fossæ** separated by the infratemp goid) ridge: above is the **temporal,** with the muscle and deep temporal nerves; below is the **infratemporal** or **zygomatic** fossa, with the lower temporal muscle, the two pterygoids, the internal maxillary vessels, a dibular division of the fifth. To the upper border of the zygom attached the temporal fascia, to its lower, the masseter. Its upper b the level of the lower lateral margin of the cerebral hemisphere. A sponding to the middle root of the zygoma, immediately in front of and on a level with the upper border of the bony meatus, is called the point. Here the superficial temporal vessels and the auriculotem cross the zygoma, and a patient's pulse may be taken by the anesth lower end of the central (Rolandic) fissure lies 5 cm. (2 in.) vertically point. The **temporal ridge,** giving origin to the temporal fascia, sta zygomatic process of the frontal, and becoming less distinct, curves backward over the lower part of that bone, crosses the coronal sutur the parietal bone, curving downward and backward to its posterior inf Here it passes on to the temporal, and passing forward over the extern meatus, is continuous with the posterior root of the zygoma. Belo of the zygoma will be felt the mandibular joint, and when the mouth the condyle will be felt to glide forward on the eminentia articularis well-marked depression behind.

The **external auditory meatus,** measured from its opening on the concha to th is about 2.5 cm. (1 in.) in length; if from the tragus, 3.7 cm. (1½ in.). Its long ax medially and a little forward with a slight convex curve upward, most marked i Between the summit of this curve and the membrane is a slight recess in which fo may lodge. The lumen is widest at its commencement, narrowest internally. cartilaginous portion in line with the bony, the auricle should be drawn well upwa ward. In the bony portion the skin and periosteum are intimately blended, thu

blood-supplies to flaps taken from the forehead. Owing to the paper-like thinness of the bones on the medial wall of the orbit, e. g., lacrimal, ethmoid, and body of sphenoid, and the mobility of the skin, injuries which are possibly penetrating ones, as from a slate-pencil, etc., are always to be looked upon with suspicion. After a period of latency of symptoms, infection of the membranes and frontal abscess have often followed. Above the supraorbital margin is the superciliary arch, and higher still the frontal eminence [tuber frontale].

FIG. 1072.—THE SKULL, SHOWING KRÖNLEIN'S METHOD OF CRANIOCEREBRAL TOPOGRAPHY. (For explanation, see text p. 1340.)



THE CRANIUM

Under this heading will be considered the scalp, the bony sinuses, craniocerebral topography and the hypophysis.

The scalp.—The importance of the **scalp** is best seen from an examination of its **layers** (fig. 1073). These are—(1) **skin**; (2) **subcutaneous fat** and **fibrous tissue**; (3) the **epicranius** (occipitofrontalis) and **aponeurosis**; (4) the **subaponeurotic layer** of connective tissue; (5) the **pericranium.**

The first three layers are connected and move together. The thick skin, supported by the dense fibrous subcutaneous layer and epicranial aponeurosis, is well adapted to protect the underlying cranium from the effects of trauma, and in this connection the mobility of the first three layers on the subaponeurotic areolar tissue is important. A scalp wound does not gape widely unless it involves the epicranial aponeurosis, in which case it involves the subjacent **'dangerous area'** of the scalp, so-called because pus in this layer may spread widely underneath the scalp and even give meningeal infection by spreading through the diploic or emissary veins. In the process of scalping (whether performed by the knife or by the hair being caught in machinery), separation takes place at this subaponeurotic layer which is loose, delicate and devoid of fat. The numerous **sebaceous glands** frequently give rise to retention cysts in the scalp.

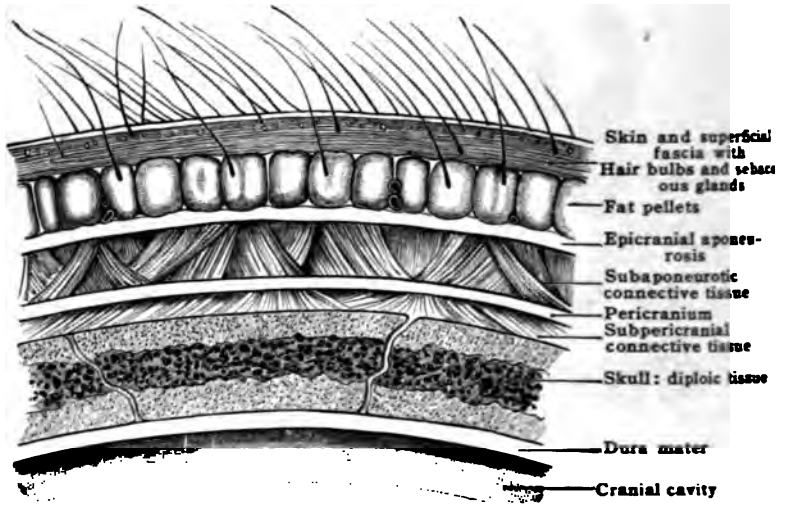
The **epicranius and aponeurosis** have been described elsewhere (p. 371).

The **pericranium** differs from periosteum elsewhere in that it gives little nourishment to the bone beneath, which derives most of its blood-supply from

the meningeal vessels. After necrosis of the skull there is no tendency to th formation of an involucrum of new subperiosteal bone as in the long bones. Th pericranium is firmly adherent to the sutures of the skull bones, so that an subpericranial effusion of blood or pus is limited by the sutures.

Of the **vessels of the scalp,** the *arteries*, arising in the anterior region fro the internal, in the posterior from the external carotid, are peculiar in the position. Thus they lie superficial to the deep fascia, which is here represente by the aponeurosis (fig. 1073). From this position arises the fact that a lar flap of scalp may be separated without perishing, as it carries its own bloo vessels. From the density of the layer in which the vessels run they cann retract and are difficult to seize, hemorrhage thus being free. Finally, fro their position over closely adjacent bone, ill-applied pressure may easily lead t sloughing. A practical point with regard to the veins is given below. Th *lymphatics* from the front of the scalp drain into the anterior auricular an parotid, those behind into the posterior auricular, occipital and deep cervic nodes. The **nerves** are derived from all three divisions of the trigeminus, fro

FIG. 1073.—SECTION THROUGH THE SCALP, CRANIUM AND DURA MATER. (Tillaux.



the facial (motor) and also from three branches of the second and third cervic (fig. 805). The supply from the fifth explains the neuralgia in acute iritis, glau coma, and herpes frontalis, and also the pains shooting up from the front of th ear in late cancer of the tongue.

The emissary veins.—These are communications between the sinuses within and the veins outside the cranium. Most of them are temporary, correspondin to the chief period of growth of the brain. Thus in early life, when the develop ment of the brain has to be very rapid, owing to the approaching closure of it case, a free escape of blood is most essential, especially in children, with the sudden explosions of laughter and passionate crying.

The gravity of these emissary veins and their free communications with others are show by the readiness with which they become the seat of thrombosis, and thus of blood-poisonin in cranial injuries, erysipelas, infected wounds of the scalp, and necrosis of the skull. The include the following (cf. pp. 950):

1. Vein through the foramen cecum, between the anterior extremity of the superior sagitt sinus and the nasal mucous membrane. The value of this temporary outlet is well seen in th timely profuse epistaxis of children. Other more permanent communications between the sk cavity and nasal mucous membrane pass through the ethmoid foramina. The fact that t nasal mucous membrane is loose and unsupported on the nasal conchæ (turbinate bone allows its vessels to give way readily, and thus forms a salutary safeguard to the brain, wardi off many an attack of apoplexy. 2. Vein through the mastoid foramen, between the transver lateral sinus and the posterior auricular and occipital veins. This is the largest, the mo constant, and the most superficial of the emissary veins. 3. Vein through the poster superior angle of the parietal between the superior sagittal sinus and the veins of the scal 4. Vein through the condyloid foramen between the transverse (lateral) sinus and the de veins of the neck. 5. Vein through the hypoglossal canal between the occipital sinus and t

deep veins of the neck. 6. Ophthalmic veins communicating with the cavernous sinus and the angular vein. These veins may be the source of fatal blood-poisoning, by conveying out of reach septic material, in acute periostitis of the orbit, or in osteitis, of dental origin, of the jaws. 7. Minute veins through the foramen ovale between the cavernous sinus and the pharyngeal and pterygoid veins. 8. Communications between the frontal diploic and supraorbital veins, between the anterior temporal diploic and deep temporal veins, and between the posterior temporal and occipital diploic veins and the transverse sinus. In addition to the veins specially mentioned, the scalp and sinuses communicate by numerous diploic veins, by those in the intersutural membrane, and through sutures before their obliteration, as already explained.

Structure of cranium.—Two layers and intervening cancellous tissue. Each layer has special properties. The **outer** gives thickness, smoothness, and uniformity, and, above all, elasticity. The **inner** is whiter, thinner, less regular—e.g., the depressions for vessels, Pacchionian bodies, dura mater, and brain. **The diploë,** formed by absorption after the cranium has attained a certain thickness, reduces the weight of the skull without proportionately reducing its strength, and provides a material which will prevent the transmission of vibrations.

A blow on the head may fracture the internal layer only, the external one and diploë escaping. This is difficult to diagnose, and thus it is impossible to judge of the severity of a fracture from the state of the external layer. This may be whole, or merely cracked, while the internal shows many fragments. It is usual to find more extensive splintering of the inner than of the outer layer (table.)

The average **thickness** of the adult skull-cap is about 5 mm. (⅕ in.). (Holden.) The thickest part is at the external occipital protuberance, where the bone is often 1.8 cm. (¾ in.) in thickness. The thinnest part of the skull vault is over the temporal part of the squamous. The extreme fragility of the skull here is partly compensated for by the thickness of the soft parts; these two facts are always to be remembered in the diagnosis of a fracture of the skull here, after a slight injury. Other weak spots are the medial wall of the orbit, the cerebellar fossæ, and that part of the middle fossa corresponding to the glenoid cavity.

Anatomical conditions tending to minimise the effects of violence inflicted upon the skull.—(1) The **density and mobility of the scalp.** (2) The **dome-like shape of the skull.** This is calculated to bear relatively hard blows and also to allow them to glide off. (3) **The number of bones** tends to break up the force of a blow. (4) The **sutures** interrupt the transmission of violence. (5) The **intersutural membrane** (remains of fetal periosteum) **acts,** in early life, as a linear buffer. (6) **The elasticity of the outer layer** (table). (7) **The overlapping of some bones,** e. g., the parietal by the squamous; and the alternate bevelling of adjacent bones, e. g., at the coronal suture. (8) **The presence of ribs, or groins,** e. g., (*a*) from the **crista galli** to the internal occipital protuberance; (*b*) from the root of the nose to the **zygoma;** (*c*) the temporal ridge from orbit to mastoid; (*d*) from mastoid to mastoid; (*e*) from external occipital protuberance to the foramen magnum. (9) **Buttresses,** e. g. zygomatic processes and the greater wing of the sphenoid. (10) The **mobility** of the head upon the spine.

THE BONY SINUSES

Frontal.—When well developed, the frontal sinuses may reach 5 cm. (2 in.) upward and 3.7 cm. (1½ in.) laterally, occupying the greater part of the vertical portion of the frontal bone. (Cf. pp. 131 and 1235). When very small, they scarcely extend above the nasal process. In any case, they are rarely symmetrical. The average dimensions of an adult frontal sinus are 3.7 cm. (1¼ in.) in height, 2.5 cm.(1 in.) in breadth, and 1.8 cm. (¾ in.) in depth. (Logan Turner.) The sinuses are separated by a septum. The posterior wall is very thin. Each sinus narrows downward into the infundibulum. This is 'deeply placed, at the back of the cavity, behind the frontal (nasal) process of the maxilla and near the medial wall of the orbit. Its termination in the middle meatus is about on a level with the palpebral fissure.' (Thane and Godlee.) Its direction is backward.

The communication of these sinuses with the nose accounts for the frontal headache, the persistence of polypi and ozena, and the fact that a patient with a compound fracture opening up the sinuses can blow out a flame held close by.

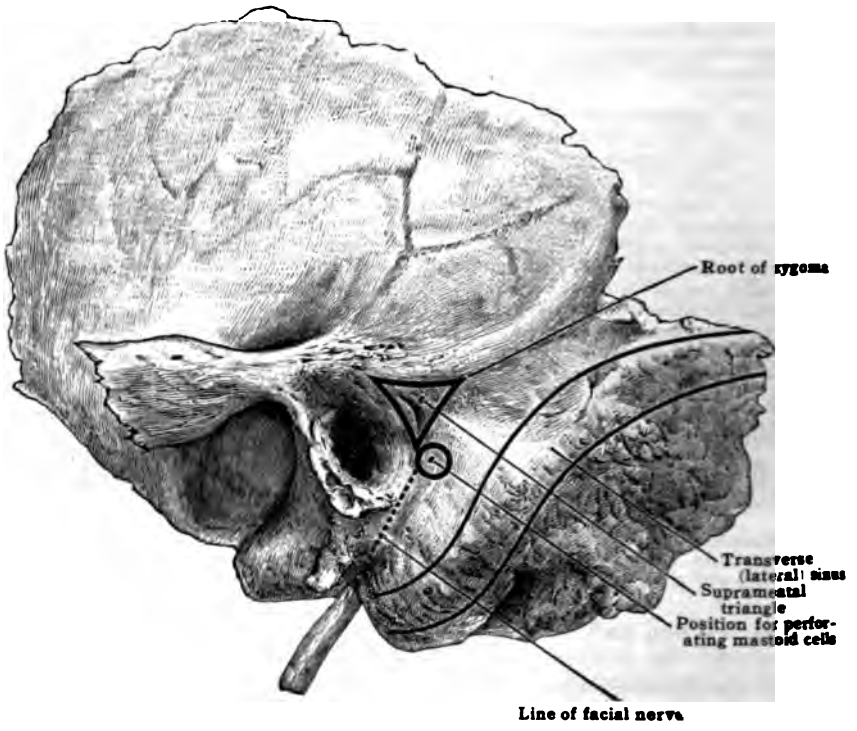
To open the frontal sinus, while the incision which leaves the least scar is one along the shaved eyebrow, superficial laterally so to avoid the supraorbital nerve and vesels, running a little downward at the medial end, it is always to be remembered that, where the sinuses are little developed, this or a median incision may open the cranial cavity. To avoid this complication the sinus should always be opened at a spot vertically above the medial angle.

The development of these by the twentieth or twenty-fifth year may render a fracture here much less grave in the adult than would otherwise be the case, the inner layer (table), if now separated from the outer, protecting the brain. Mr. Hilton showed that the absence of any external prominence here does not necessarily imply the absence of a sinus, as this may be formed by retrocession of the internal layer. Again, prominence of the superciliary and frontal eminences does not necessarily point to the existence of a sinus at all, being due merely to a heaping up of bone.

The mastoid cells are arranged in two groups;—(A) The **upper, or antrum,** present both in early and late life, horizontal in direction, closely adjacent to and communicating with the tympanum. (B) The **lower, or mastoid cells proper.** This group is not developed in early life.

A. **Tympanic antrum** (fig. 1075).—This is a small **chamber lying** behind the tympanum, into the upper and back part of which (**epitympanic recess**) it opens (cf. p. 147). Its size varies, especially with age. **Almost as large at birth,** it reaches its maximum (that of a pea) about the **third or fourth year.** After this its size usually diminishes somewhat, owing to the development of the encroaching bone around it. Its **roof,** or tegmen, is merely the backward continuation of the

FIG. 1074.—TEMPORAL BONE, SHOWING SUPRAMEATAL TRIANGLE. (BART.)
The lower part of the transverse sinus is here placed too far back to be relied upon with constant accuracy.



tegmen tympani. The level of this is indicated by the **posterior root of the zygoma.** 'The level of the floor of the adult skull at the tegmen antri is, on an average, less than one-fourth of an inch above the roof of the external osseous meatus; in children and adolescents, from one-sixteenth to one-eighth of an inch.' (Macewen.) In early life, when the bony landmarks, e.g., the suprameatal crest are little marked, the level of the upper margin of the bony meatus (suprameatal triangle, fig. 1074) will be the safest guide to avoid opening the middle fossa.

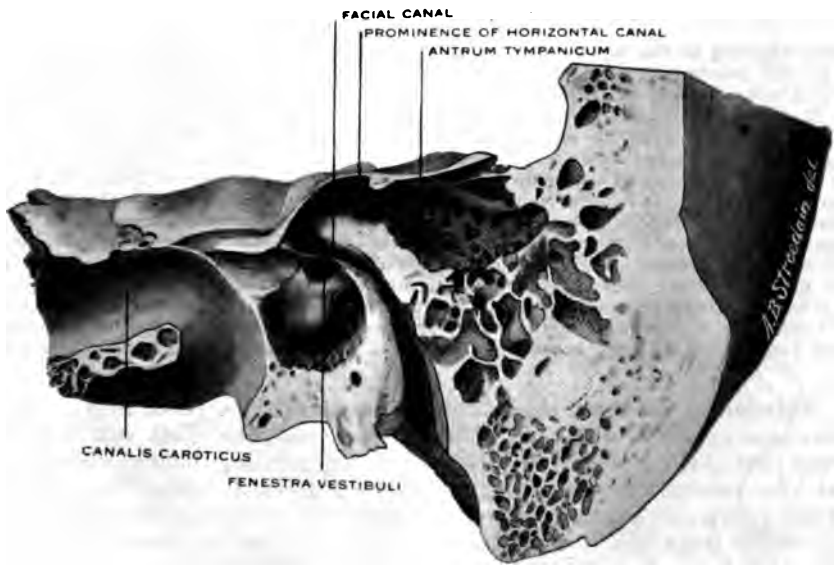
The **lateral wall** of the antrum is formed by a plate descending from the squamous bone. This is very thin in early life, but as it develops by deposit under the periosteum, the depth of the antrum from the surface increases. Macewen gives the average of the depth as varying from one-eighth to three-fourths of an inch.

The thinness of the outer wall in early life is of practical importance. It allows of suppuration making its way externally—subperiosteal mastoid abscess. This will be facilitated by any delay in the closure of the petro- and mastosquamosal sutures, by which this thin plate blends with the rest of the temporal bone. Further, by the path of veins running through these sutures or their remnants, infection may reach such sinuses as the inferior petrosal. The sutures normally close in the second year after birth.

Through the **floor,** the antrum communicates with the lower cells of the mastoid. This floor is on a lower level than the opening into the tympanum, and thus drainage of an infected antrum is difficult, fluid finding its way more readily into the lower cells. **Behind** the mastoid antrum and cells is the bend of the sigmoid part of the transverse (lateral) sinus, with its short descending portion (figs. 1074, 1078). The average distance of the sinus from the suprameatal triangle is 1 cm. (⅖ in.). It may be further back; on the other hand, it may come within 2 mm. (1/12 in.) from the meatus, and even overlap the outer wall of the antrum.

The exact position of the antrum, a little above and behind the external auditory meatus is represented by Macewen's 'suprameatal triangle.' This is a triangle bounded by the posterior root of the zygoma above, the upper and posterior segment of the bony external meatus below, and an imaginary line joining the above boundaries (fig. 1074). 'Roughly speaking, if the orifice of the external osseous meatus be bisected horizontally, the upper half would be on the level of the mastoid antrum. If this segment be again bisected vertically, its posterior half would again correspond to the junction of the antrum and middle ear, and immediately behind this

FIG. 1075.—SECTION THROUGH MASTOID PROCESS, ANTRUM AND TYMPANIC CAVITY. (Dr. Geo. E. Shambaugh.)



lies the suprameatal fossa.' (Macewen.) When opening the antrum through this triangle, the operator should work forward and medially, so as to avoid the transverse sinus (fig. 1074, 1078); while, to avoid the facial nerve (fig. 1075), he should hug the root of the zygoma and the upper part of the bony meatus as closely as possible. The level of the base of the brain will be a few mm. above the posterior root of the zygoma (fig. 1076) and about 6 mm. (¼ in.) above the roof of the bony meatus. (Macewen.)

B. The lower **mastoid cells** are developed later than is the antrum, and vary much in their contents. The condition of the mastoid cells varies very widely. They may be numerous (fig. 1075) or few. In the latter case they are replaced by diploë, or by bone which is unusually dense, without necessarily any pathological change. Hence mastoids have been classified as pneumatic, diploëtic, or sclerosed.

As part of the surgical anatomy of this most important region, the different paths by which infection of the tympanum and antrum may travel should be glanced at. The most important are:—(1) **Upward**: either by advancing caries or by infection of veins going to the superior petrosal sinus, or through the tegmen to the membranes; an abscess forming in the temporal lobe, usually the middle and back part. (2) **Backward**: the transverse (lateral) sinus and cerebellum (abscess of the front and outer part of the lateral lobe) are reached in the same ways as those given above, the mastoid vein being the one chiefly affected here. Macewen has shown that the bony wall of the sinus, like those of the tegmen and the aqueduct of Fallopius, may be naturally imperfect. (3) **Downward**: where the vertical cells are well developed mischief may reach the mastoid notch and cause deep-seated inflammation beneath the sternomastoid. (v. Bezold's abscess.) (4) **Lateralward**: the explanation of this, in early life, has been given above. (5) **Medialward**: the facial nerve, or by the fenestra ovalis; the labyrinth is now in

danger. When the internal ear and auditory nerve are affected, infection finds another ju to the cerebellar fossa.

The **sphenoidal sinuses** are less important surgically, but these points should be rem bered:—(1) Fracture through them may lead to bleeding from the nose, which is thus bro into communication with the middle fossa; (2) the communication of their mucous membra with that of the nose may explain the inveteracy of certain cases of polypi and ozæna; and in the frontal sinuses very dense exostoses are sometimes formed. Before any operat attack on these sinuses is undertaken, their most important relations should be remembe Thus above are the olfactory and optic nerves, the hypophysis (see p. 1342), and front of the po Externally lie the cavernous sinus and superior orbital (sphenoidal) fissure. Below is the r of the nose.

The relations of the various paranasal sinuses, including the **ethmoidal** and **maxill sinuses** are considered more in detail in connection with the sections on OSTEOLOGY and es cially the RESPIRATORY SYSTEM (pp. 1233).

CRANIOCEREBRAL TOPOGRAPHY

To make as clear as possible the points of practical importance which have late years, been put on a definite basis, and which the surgeon may have to re and act upon at very short notice, craniocerebral topography will be spoken under the following headings: A. **Relation of the brain as a whole to the sk** B. **Localization and relations of the chief sulci and gyri to the skull.**

Before alluding to the above, it is necessary to say distinctly that the following surf markings and points of guidance are only approximately reliable, for the following reas (1) In two individuals of the same age and sex the sulci and convolutions are never preci alike. (2) The relations of the convolutions and sulci to the surface vary in different indi uals. For age differences, cf. figs. 745 and 746. (3) That as the surface area of the s and outer aspect of the skull are greater than the surface area of the brain, and as the convex do not tally, lines drawn on the scalp or skull cannot always correspond precisely to cere convolutions or sulci. It results from the above that when a definite area of the surface is to correspond accurately in any individual to a definite area of the brain surface, this re has been correlated from many examinations; and that as surface-markings, shape, and proce of skull and arrangement of surface are all liable to variations in different individuals. surgeon must allow for these variations by removing more than that definite area of s which is said to correspond exactly to that part of the brain which he desires to expose. detailed relations of craniocerebral topography are not emphasized so much as formerly, h ever, for large flaps are now turned down so as to expose larger areas of the brain for ex ination.

A. **Relation of the brain as a whole to the skull** (figs. 1076, 1077).—To tr *the lower level of each cerebral hemisphere* on the skull, the chalk would start fr the lower part of the glabella; thence the line representing the lower borders of t frontal lobe pursues a course, slightly curved upward, about 0.8 cm. ($\frac{1}{3}$ i above the supraorbital margin; next, crossing the temporal crest about 1.2 c ($\frac{1}{2}$ in.) above the zygomatic (external angular) process, it passes not quite ho zontally but descending slightly to the region of the pterion (Sylvian point) the temporal fossa about 3.7 cm. ($1\frac{1}{2}$ in.) behind the zygomatic process. Fr this point the line of the level of the brain, now convex forward and correspondi to the anterior extremity of the temporal lobe, would dip down, still within t great wing of the sphenoid, to about the center of the zygoma. Thence the li of the lower border of the temporal lobe would travel along the upper border this process about 6 mm. ($\frac{1}{4}$ in.) above the roof of the external auditory meat (fig. 1076), and thence just above the base of the mastoid and the posterior i ferior angle of the parietal, and so along the linea nuchæ suprema, and correspon ing to the tentorium and horizontal part of the transverse (lateral) sinus, tot external occipital protuberance.

The **upper margin of each hemisphere** would be represented by a line drav from just below the glabella, sufficiently to one side of the midline to allow f the falx and superior sagittal sinus, to the inion. The *cerebellum* occupies th posterior cranial fossa, below the cerebral hemisphere, and behind the ear (fig 1076, 1077).

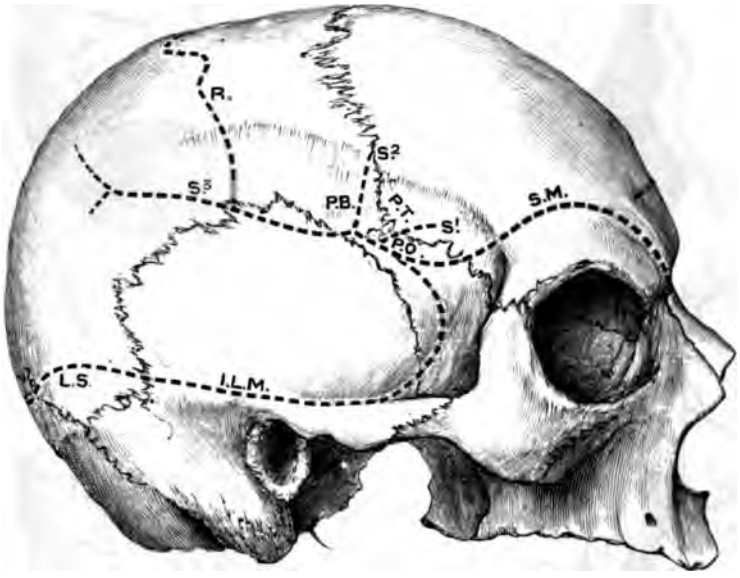
B. **Localization and relations of the chief sulci and gyri.**—It will be well fir to indicate the position of the chief sutures which mark off the parietal bon under which lies that part of the brain which is most important to the surgeon- the motor area. The upper limit of the bone will be indicated by the line alread spoken of as giving the upper margin of the hemisphere—the **sagittal line,** c **sagittal suture.** The anterior limit of the parietal bone, formed by the coron **suture,** may be traced thus: The point where it leaves the sagittal suture (th

bregma) will be found by drawing a line from a point just in front of the external auditory meatus (the preauricular point) (fig. 1072) straight upward on to the vertex; from this point a line drawn downward and forward to the middle of the zygomatic arch would indicate that of the coronal suture. Under this suture lie the posterior extremities of the three frontal convolutions; for the frontal lobe lies not only under the frontal bone, but extends backward under the anterior part of the parietal, the central sulcus (fissure of Rolando), which separates the frontal from the parietal lobe, lying from 3.7 to 5 cm. (1½ to 2 in.) behind the coronal suture at its upper extremity and about 2.5 cm. (1 in.) at its lower.

The squamoparietal suture, which marks the lower border of the anterior two-thirds of the parietal bone, is not so easy to define, owing to the irregularity and variations of its curve. Its highest point is usually 4.3 cm. (1¾ in.) above the zygoma.

FIG. 1076.—THE OUTLINE OF THE CEREBRUM IN RELATION TO THE SUTURES. (Cunningham.)

S.M. Superciliary margin of the cerebrum. I.L.M. Inferolateral margin of the cerebrum. L.S. Position of highest part of the arch of the transverse sinus. R. Central sulcus (Fissure of Rolando). s^1. Anterior horizontal limb of lateral fissure. s^2. Anterior ascending limb of lateral fissure. s^3. Posterior horizontal limb of lateral fissure P.B. Opercular portion of the inferior frontal convolution. P.T. Triangular portion of the inferior frontal convolution. P.O. Orbital portion of the inferior frontal convolution.



The lambdoid suture, which forms the posterior boundary of the parietal bone, will be marked out by a line which starts from a point (lambda) about 6.2 cm. (2½ in.) above the external occipital protuberance, and runs downward and forward to a point on a level with the zygoma, 3.7 cm. (1½ in.) behind and 1.2 cm. (½ in.) above the center of the meatus.

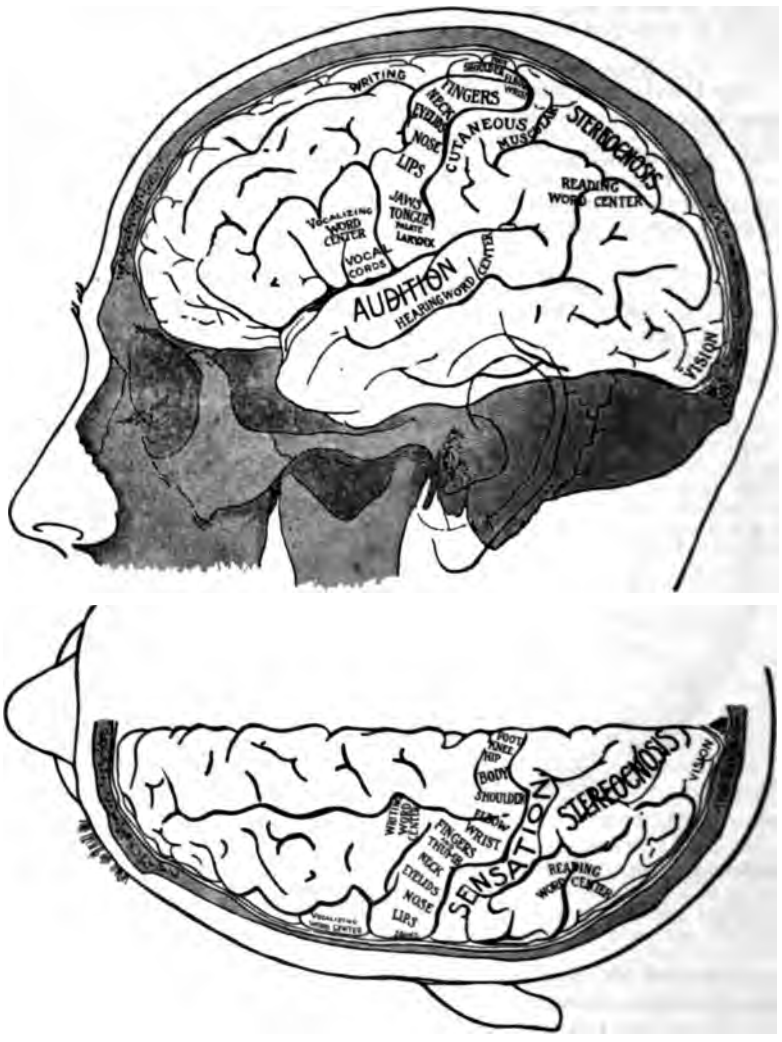
The position of the chief sulci (fissures) will now be given;—

Lateral (Sylvian) fissure (fig. 1076).—The point of appearance of this, on the outer side of the brain, practically corresponds to the pterion (fig. 1072)—a point which lies in the temporal fossa, about 3.7 cm. (1½ in.) behind the zygomatic process and about the same distance above the zygoma. From this point the lateral fissure, which here separates the frontal and parietal from the temporal lobe, runs backward and upward, ascending gently, at first in the line of the squamoparietal suture, then crossing this suture about its center and thence, ascending more rapidly, it climbs up to the temporal ridge, to end 1.8 cm. (¾ in.) below the parietal eminence. Its termination is surrounded by the supramarginal convolution, to which the parietal eminence corresponds with sufficient accuracy. Such being the surface-marking of the chief or posterior horizontal limb of the lateral fissure (s^3, fig. 1076), it remains to indicate briefly the two shorter limbs which bound the inferior frontal convolution, which, on the left side, contains the center for speech (Broca's convolution), and corresponds to a point lying three fingers' breadth vertically above the center of the zygo-

matic arch. (Stiles.) Of these, the anterior horizontal (s^1, fig. 1076) runs fo ward across the termination of the coronal, just above the line of the spheno parietal suture. The ascending limb (s^2, fig. 1076) runs upward for about 2 cm. (1 in.) just behind the termination of the coronal suture, or 3.7 cm. ($1\frac{1}{2}$ in behind the zygomatic process.

The central sulcus (fissure of Rolando).—This most important fissure, i front of which, in the precentral convolution of the frontal lobe, lie the moto

FIG 1077.—CEREBRAL TOPOGRAPHY AND LOCALIZATION. (Cushing, from Keen's Surgery.)



centers for the opposite side of the body, is situated under the parietal bone It may be marked out with sufficient precision in the following way (Thane) The sagittal line, from glabella to external occipital protuberance, is bisected and a point 1.2 cm. ($\frac{1}{2}$ in.) behind the center represents the superior Rolandic point. From this point a line drawn downward and forward 9 cm. ($3\frac{3}{4}$ in.) long at an angle of $67\frac{1}{2}°$ with the sagittal line (i.e., $\frac{3}{4}$ of a right angle) will represent the central sulcus. The lower extremity of this line is known as the inferior Rolandic point.

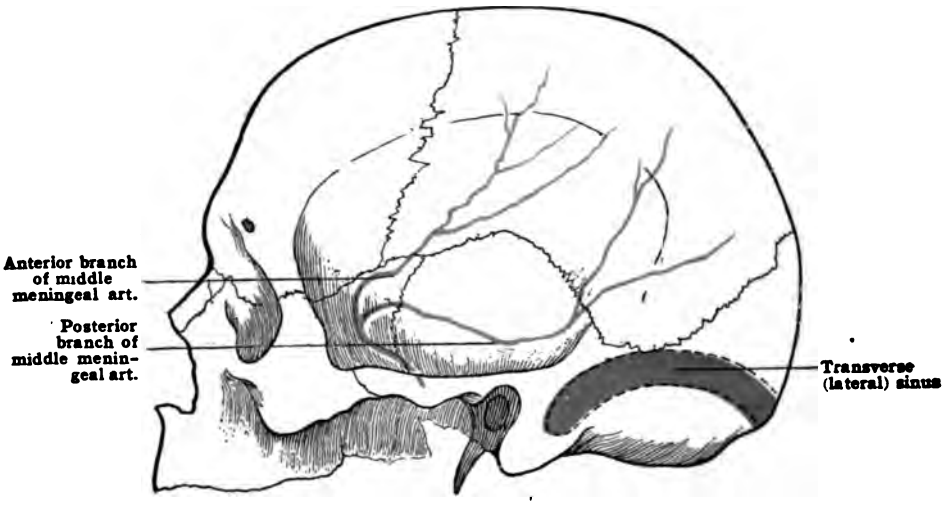
This method is open to the objection that it only applies to the average adult skull, and not to skulls of all sizes. To obviate this difficulty the method of Krönlein may be employed in addition (fig. 1072). Reid's base line BL is drawn through the lower border of the orbit and the upper border of the external acoustic meatus. Parallel to this an upper horizontal line UH is

marked out at the level of the upper margin of the orbit. Three lines vertical to the base line are now drawn, (1) at the posterior border of the mastoid process MR_1 (2) through the condyle of the lower jaw (CR_2), and (3) from the midpoint of the zygoma (ZS). The point R_1, where the first vertical joins the sagittal suture is the superior Rolandic point. The point S where the third vertical ZS cuts the line UH marks the junction of the three limbs of the lateral fissure. A line joining R and S will cut the second vertical CR_2 at the inferior Rolandic point, R_2.

The posterior limb of the lateral fissure also may be represented by a line bisecting the angle R_1SH and ending behind at the point S^1 where it cuts the vertical MR_1.

Reid's base line (fig. 1072, BL) is of importance in craniocerebral topography. The sigmoid portion of the *transverse (lateral) sinus* is at a point on the base line ¾ of an inch behind the center of the meatus. The transverse portion of the sinus is at a point an inch behind the meatus and ¼ of an inch above the base line. The *mastoid antrum* is at a point formed by the meeting of Reid's base line with a vertical line through the posterior border of the meatus (in the suprameatal triangle, fig. 1074). The trephine opening for *cerebral abscess* (temporosphenoidal) is ¾ of an inch above the base line at the posterior border of the meatus. The trephine opening for *cerebellar abscess* should be made an inch and a half behind the meatus on Reid's base line and ¼ of an inch below it. The relation to the lateral ventricle is mentioned below.

FIG. 1078.—LATERAL VIEW OF THE SKULL, SHOWING THE TOPOGRAPHY OF THE MIDDLE MENINGEAL ARTERY AND THE TRANSVERSE SINUS.



Some further *points in the surgical anatomy of the cranium* must be considered. The *middle meningeal artery*, entering the middle cranial fossa by the foramen spinosum, grooves the great wing of the sphenoid and divides into two branches (fig. 1078). The anterior grooves the anterior inferior angle of the parietal bone, and is then continued upward and slightly backward between the coronal suture and central sulcus, almost to the vertex; the posterior branch takes a lower level, running backward under the squamous bone to supply the parietal and anterior part of the occipital bones. If a skull, bisected anteroposteriorly, be held up to the light, it will be seen how thin are the bones over the chief branches of this vessel, thus accounting for the slight violence sometimes sufficient to rupture it. The groove it occupies in the parietal is sometimes converted into a canal. A wounded artery retracting here may be very difficult to secure. The veins which accompany the artery and which lie lateral to it in the groove are thin-walled and sinus-like before they open into the sphenoparietal sinus, another explanation of the obstinacy of this hemorrhage. According to the point of rupture, three hematomata should be remembered (Krönlein), anterior or frontotemporal; middle, or temporoparietal; and posterior, or parietooccipital. The first two are much the most frequent, and exposure of the pterion, with free removal of the adjacent bones will suffice for dealing with them.

Drainage of the lateral ventricle.—(1) Where the anterior fontanelle is closed, Poirier and Keen have opened the inferior cornu through the middle temporal convolution, the pin of the trephine being placed 3.1 cm. (1¼ in.) behind the external auditory meatus, and about the same distance above Reid's base line. The needle should here be directed to a point about 5 cm. (2 in.) above the opposite ear. (2) Kocher's point for draining the lateral ventricle is taken over the frontal lobe 2.5 cm. from the median line and 3 cm. in front of the upper Rolandic point. The needle is passed downward and a little backward to a depth of 4 or 5 cm.

Puncture of the corpus callosum is employed to lessen intracranial pressure in cases of inoperable or unlocalized brain-lesions where there is an internal hydrocephalus. A communication is thus established between the ventricles and the subdural space. The anterior and middle thirds of the corpus are the best sites as the corpus is thinnest and the lateral ventricle on one or the other side is sure to be opened. The callosum is usually punctured at a point a finger's breadth behind the bregma and to the side in order to avoid the superior sagittal sinus.

Up to this point the **outside** of the cranium has been mainly considered; it remains to draw

attention to some of the chief points in the surgical anatomy of the interior, especially of t base. The three fossæ are of paramount importance in fractures. In the anterior fo the delicacy of parts of the floor, the connection of this with the nose and orbit, and the ex adaptation of its irregular surface to that of the frontal lobes, no 'water-bed' intervening, the chief points. Thus the slightness of a fatal fissure, the frequent presence of bruising af a blow perhaps on the occiput, which has been considered to have caused only concussion, characteristic palpebral hemorrhage, and the infection of a fracture here are all explain together with the possibility and gravity of a fracture here from a severe blow on the nose. the middle fossa the frequency of fractures is explained by the facts that while here, as in other fossæ, a fracture often radiates down from the vertex, the overlying vault being a reg often struck, the base is weakened by numerous foramina and fissures. Further, the resist power of the petrous bone must be lessened by the cavities for the internal ear, the caro and, to a less degree, by the jugular fossa. For fluids to escape through the external mea the dura, the prolongation of the arachnoid into the internal meatus, the membrani tymp and probably the internal ear, must all be injured. The presence of the middle meningeal art (fig. 1078) and the cavernous sinus in this fossa must also be remembered, especially in s operations as that on the Gasserian ganglion. Posterior fossa: It is not sufficiently recogni that fractures here are, owing to the anatomy of the parts, in some respects the most import of all. It is here that a small fissure-fracture, ultimately fatal, with severe occipital and fro bruising and some intradural hemorrhage, has been so often overlooked, especially in drunken. This is explained by the supposed strength of the bone, this being really very thi places, by the thickness of the soft parts, and the abundance of hair. Further, there is no v apparent escape of cerebral contents as in the anterior and middle fossæ. Blood, etc., n trickle into the pharynx far back, or a deep-seated ecchymosis coming up after two days, un the muscles about the mastoid process, may call attention to the damage within.

Dura mater.—The outer layer of this membrane acts as a periosteum, by bringing blo vessels to the bone, while the inner layer supports the brain. The influence of its partitions a its damping effect on vibrations is great in blows on the head. Its varying adhesions, accord to site and age, must be remembered. Thus while it is intimately connected over the b with its adhesions to the different foramina, it is more loosely connected with the vault, a shown in middle meningeal hemorrhage. In early and later life the closeness of its connecti with the bones is also more marked. It is united to the inter-sutural membranes.

Finally, the existence of the cerebrospinal fluid with its power of lessening the evil of brations and its aid in regulating intracranial pressure, must be borne in mind. The ch collections, in which the subarachnoid meshwork is almost absent, are met with in front a behind the medulla. That in front, also lying under the pons, Hilton's 'water-be ,' sen a prolongation forward to the optic chiasma, but does not extend under the frontal or tempo lobes. The collection behind lies between the medulla and under surface of the cerebellu Here, by the foramen of Magendie, the intraventricular cavities communicate with the su arachnoid space of the brain and spinal cord.

The hypophysis cerebri.—The hypophysis (pituitary body) has assumed ne clinical importance because of recent experimental and clinical studies. It li in the sella turcica (figs. 1068–1070) and consists of three parts: the pars anteri and pars intermedia, both of which are derived from buccal ectoderm, and t pars nervosa which is composed of nervous tissue, a downgrowth from the flo of the third ventricle. Its structure is described under GLANDS OF INTERNA SECRETION, p. 1326.

Apart from the general skeletal and nutritional changes (acromegaly and Fröhlich's sy drome), which are caused by alteration in the function of the gland, pressure-effects up neighboring structures, especially upon the optic nerve and adjacent bones, are noted as t gland enlarges. The anterior lobe as it enlarges is apt to erode and expand the floor of the sel pushing toward the sphenoidal sinus. Interpeduncular tumors on the other hand widen t entrance to the sella, causing destruction of the clinoid processes. The enlargements may detected by lateral radiograms. The normal size of the adult hypophyseal fossa is 10 to 12 m from before backward and 8 mm. from above downward.

There are three surgical approaches to the hypophysis. In one, employed by Cushin Kanavel and Halsted, a sublabial incision is made in the vestibule of the mouth and through the mucosa is separated from each side of the nasal septum back to the sphenoidal sinus. submucous resection of the septum is then made, the floor of the sphenoidal sinus is remove the hypophyseal fossa is opened and a part of the gland removed. The frontal approach to t hypophysis (McArthur and Frazier) is used by many because of the lessened risk of infectio In this operation a plastic operation is performed upon the frontal bone, the optic foramen located and the dura incised at this level to permit of exposure of the hypophysis. In Heue operation a large flap is turned down on the side and front of the skull and an intradural a proach is employed. Text-books upon operative surgery or special articles dealing with the should be consulted for details.

THE FACE

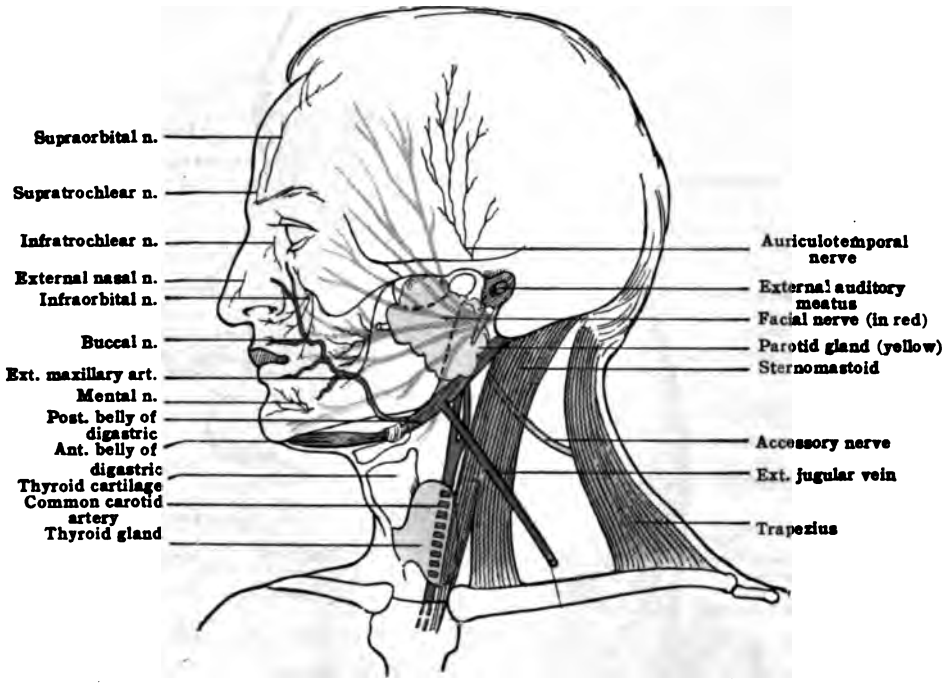
The topics included under this heading are the arteries, parotid region, nerve mandible and maxilla, orbit, mouth, palate and nose.

The outline of the different bones nasal, upper and lower jaws, zygomati and zygoma can be readily traced. The last mentioned and the glabella a

alluded to on pp. 1331 and 1332; and the canine fossa should be identified as one of the antral routes. The delicacy, laxity, and vascularity of the skin are of great importance in all operations, while the abundance of large gland orifices accounts for the frequency of lupus here.

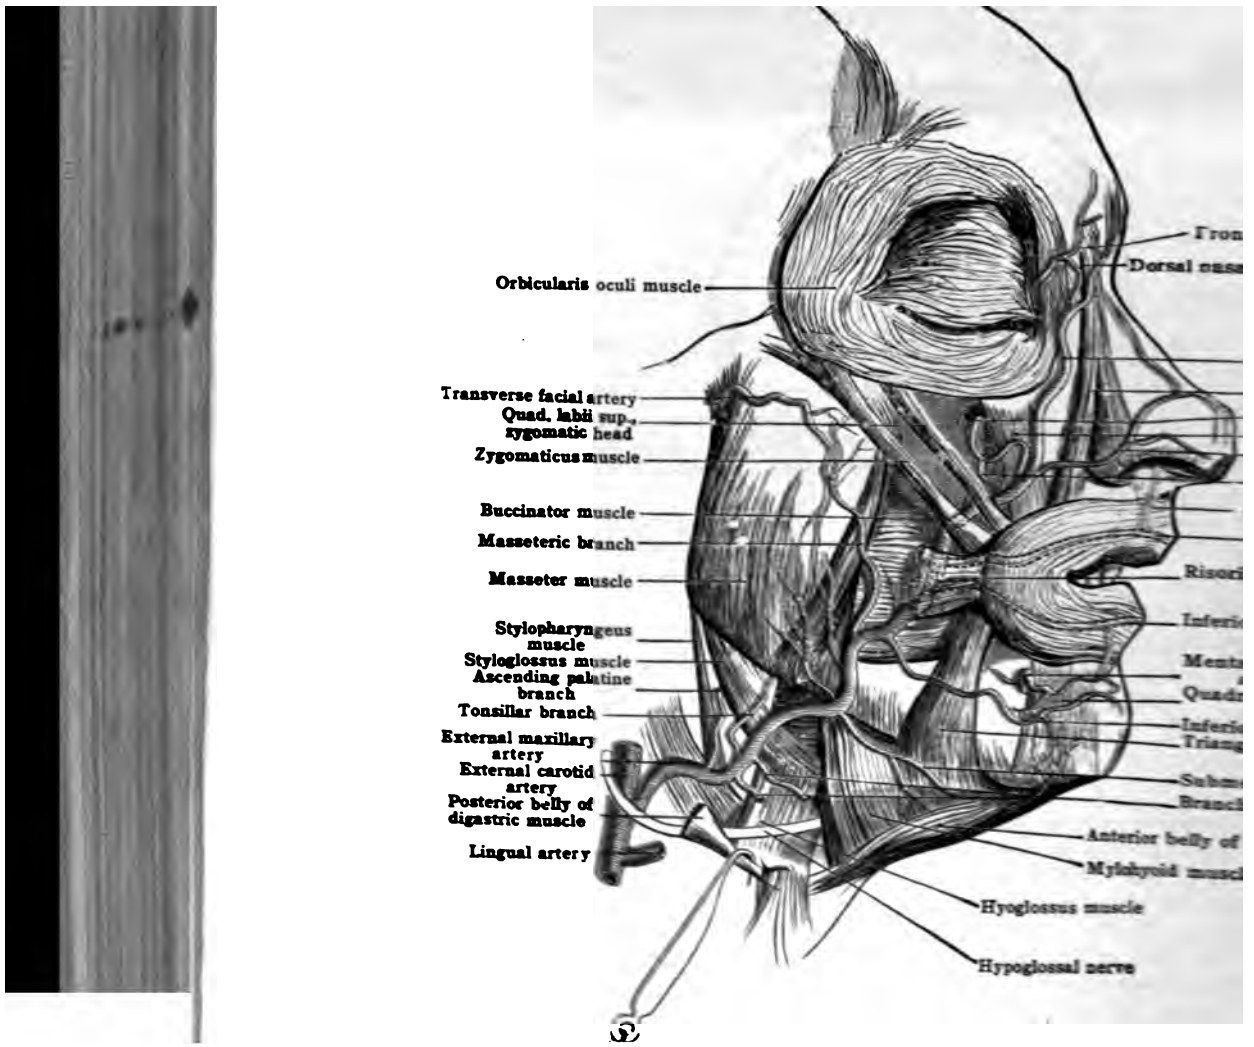
Arteries.—The **supraorbital artery** can be felt beating just above its notch (junction of medial with lateral two-thirds of supraorbital margin); the small **frontal artery** is of importance, as it nourishes the flap when a new nose is taken from the forehead; the **superficial temporal,** accompanied by the auriculotemporal nerve, can be felt where it crosses the root of the zygoma just in front of the tragus, its anterior branch about 3.1 cm. (1¼ in.) above and behind the zygomatic process of the frontal; the **occipital,** accompanied by the great occipital nerve (fig. 494), pulsates to the medial side of the center of a line drawn from the occipital protuberance to the mastoid process; the **posterior auricular,** rather deeply, between the auricle and the mastoid process. The **external carotid** lies behind

FIG. 1079.—SURFACE RELATIONS OF VESSELS AND NERVES IN LATERAL VIEW OF THE FACE AND NECK.



the ascending ramus of the mandible. The **external maxillary** (facial) (figs. 1079, 1080) crosses the jaw just in front of the masseter; if divided, both ends must be ligated here. It can be felt again a little behind the angle of the mouth, just beneath the mucous membrane (where it gives off the labial branches, which can also be felt, lying deeply, if the lip is taken between the finger and thumb); and again by the side of the nose, as it runs up to the medial angle (canthus) of the eye. The small angular branch is, from its position, always troublesome to secure. To trace the course of the **external maxillary** artery a line should be drawn from a point a little above and lateral to the tip of the great cornu of the hyoid to the lower part of the anterior border of the masseter, and thence to one lateral to and above the angle of the mouth, and so onward, lateral to the angle of the nose, up to the medial angle. The **anterior facial vein** (fig. 562) takes a straight course behind the tortuous external maxillary artery. The absence of valves and its communication by the angular and ophthalmic veins with the cavernous sinus, and, by the deep facial, with the pterygoid plexus, are of grave importance in infective thrombosis. The external jugular vein will be mentioned later.

Parotid region.—A line drawn from the lower border of the meatus to a point midway between the nose and upper lip gives the level of the **parotid** (Stenson's)



Orbicularis oculi muscle
Transverse facial artery

Hyoglossus muscle
Hypoglossal nerve

and sternomastoid; *in front* the gland and socia parotidis overlap the posterior part of the masseter, to a variable degree.

Sensory nerves.—The cutaneous nerve areas of the face are shown in figs. 805, 1079. The **supraorbital** nerve, the main sensory branch of the ophthalmic, emerges from the orbit with its companion artery through the notch (occasionally a foramen) at the junction of the medial third and lateral two-thirds of the supraorbital margin. A line drawn from the supraorbital notch downward across the interval between the bicuspid teeth will cross the **infraorbital foramen** from which emerges the **infraorbital nerve,** the main terminal division of the maxillary, at a point 1 cm. below the orbital margin. The mental foramen, the point of exit of the *mental nerve*, a branch of the inferior alveolar, is found on a prolongation of the same line midway between the upper and lower margins of the mandible in the adult.

In the infant in whom the alveolar element of the jaw is relatively large, the mental foramen is nearer the lower margin, while in the edentulous jaw of old age it is found much nearer the upper margin. In trephining to expose the inferior alveolar (dental) nerve, one of the common seats of neuralgia and one in which a peripheral operation is justified from the results, the ascending ramus is opened midway between its anterior and posterior borders, on a level with the last molar.

The **semilunar (Gasserian) ganglion** lies at a depth of 5.5–6 cm. (2¼ in.) under the eminentia articularis. In exposing it for the purpose of excision for intractable neuralgia the following structures are encountered: (1) Skin and superficial fascia with branches of the superficial temporal artery; (2) temporal fascia and muscle with deep temporal vessels; (3) squamous bone and great wing of sphenoid, which are trephined, the floor of the middle fossa being gouged away; (4) middle meningeal vessels and dura mater. By elevating the dura mater and superimposed temporal lobe, and securing the middle meningeal artery, the ganglion is exposed, lying in a separate compartment [cavum Meckelii] of the dura, which contains cerebrospinal fluid. The motor nerve of the muscles of mastication lies on the lower and medial aspect of the ganglion, and should not be divided. Division of the sensory root of the ganglion is a simpler operation than removal of the ganglion and the results are more satisfactory.

Injection of the mandibular nerve with alcohol, by means of a long stout hypodermic needle is practised in cases of intractable neuralgia as an alternative to excision of the semilunar ganglion. A vertical line is drawn on the cheek downward from the junction of the posterior and middle thirds of the zygomatic arch, and the needle is entered on this line at a point 1.5 cm. from the lower border of the zygoma. It is directed upward and medially so as to pass through the lowest part of the mandibular notch. If the mouth is opened the notch is depressed and more room gained. The needle impinges first against the inferior surface of the great wing of the sphenoid bone, and when the point is lowered a little it engages in the foramen ovale at a depth of 4–4.5 cm. In most cases the needle can be passed through the foramen ovale into the semilunar ganglion. (Harris. Lancet, Jan. 23, 1912.)

The **maxillary nerve** may be injected by passing a needle along the floor of the orbit from its inferolateral angle in a direction backward and slightly medially to the foramen rotundum which lies 4.5 cm. from the surface.

Facial nerve.—In the petrous bone the course of this nerve is first outward and forward, then, having entered the facial canal, backward and downward along the medial wall of the tympanum, above the fenestra ovalis. Emerging from the stylomastoid foramen the nerve takes first the line of the posterior belly of the digastric, running forward and a little downward from the anterior border of the mastoid where this meets the auricle (Godlee.) Entering at once the posterior part of the parotid, it crosses the neck of the mandible at the level of the lower border of the tragus (figs. 770, 1079).

The frequent paralysis of this nerve may thus depend upon—(1) cerebral causes; (2) disease of or injury to the petrous portion; (3) affections after its exit—Bell's paralysis. A diagnosis may be arrived at by attention to the following. In *cerebral disease* the lower part of the face is chiefly affected, the eyelids usually escaping. In paralysis due to involvement of the upper motor centers the orbicularis oculi, frontal and corrugator muscles are not affected. Hemiplegia of the opposite side of the body and paralysis of the sixth nerve are usually present. In all the other forms the whole side of the face is paralyzed. In *petrous paralysis*, owing to involvement of the chorda tympani, there may be interference with the saliva and taste, affecting especially the anterior part of the tongue. The auditory nerve may also be affected. Here and in (3) there will be a history of disease or injury. In complete paralysis the smooth side of the face and forehead, the absence of power of expression, to frown, to blow, or whistle, the open eyelids and epiphora, and subsequent liability to mischief in the cornea, the dropping of the angle of the mouth and dribbling of saliva, the interference with mastication from paralysis of the buccinator, are the chief points. For the relations of the facial nerve and parotid gland, see p. 1146.

Mandible.—Dislocation of the mandibular joint is referred to on p. 260. In the usual **dislocation,** from muscular action, the jaw is suddenly brought forward against the anterior part of the capsule, which tends, by the action of the

depressors, to give way; the elevators then pull up the **mandible**, a sequence t must be remembered in reduction. In the commonest **fracture** of the mandibl unilateral, near the mental foramen—the larger anterior **fragment** will be pu by the depressors downward and medially, the smaller **posterior** one upw and usually lateral to the other fragment.

Maxilla.—The boundaries of the **maxillary sinus** (**antrum**) are of much portance. The base of this irregularly pyramidal cavity corresponds to middle and inferior meatuses on the lateral wall of the **nose**; toward the up and back part is the opening into the middle meatus. The **apex** runs later toward the zygomatic process. The roof is formed by the **orbital plate** with infraorbital nerve and vessels anteriorly; the floor by the **junction of the alve** arch, carrying the first molars (and often the bicuspids), **with the hard pal** It may be pierced by the roots of the second bicuspid or **first and second m** teeth. Anteriorly, the antrum is in relation with the **canine fossa**; posteric with the zygomatic fossa. The cavity, present at birth, **increases gradually** to the twelfth year. (For further details, see p. 1235).

The chief paths of infection are through the teeth (especially the **first and second mo** the nose, and frontal sinus. The obstinacy of inflammation here is explained by the site of opening, high up on the medial wall, and thus inadequate drainage, by the imperfectly m locular cavity of the interior and its rigid walls. The chief sites for *opening the antrum* are— through the sockets of the first or second molars; (*b*) through the canine fossa, after the ref tion of mucous membrane has been detached, midway between the roots of the teeth and infraorbital foramen (this path gives more room); (*c*) through the inferior meatus of the n

THE ORBIT AND EYE

The **bony orbit** (figs. 842–845, 975) is a pyramidal fossa with its **base** at t orbital margin and its **apex** at the optic foramen. The medial walls of the tw orbits are approximately parallel, but the lateral walls diverge as they are trac forward and lie at right angles to each other. The thin **floor** which is form mainly by the maxilla and corresponds to the roof of the maxillary sinus, readily destroyed by growths extending up from the sinus and in the proce pressure on the infraorbital nerve is apt to cause pain referred to the cheek. Th **roof** formed by the orbital plate of the frontal bone is also thin, and foreign bodie thrust into the orbit may perforate it and enter the frontal lobe of the cerebrum The **medial wall** is chiefly constituted by the lacrimal and lamina papyracea o the ethmoid, both very thin bones.

Injuries of the medial wall such as may be associated with fractures of the nose bring th ethmoidal air cells into communication with the cellular tissue of the orbit. The latter may thu be distended with air on attempting to blow the nose. This wall is readily destroyed by mal ignant growths of the nose.

The **lateral wall** is formed in its anterior third by the zygomatic bone, whic separates the orbit from the zygomatic fossa. The posterior **two-thirds** formed by the sphenoid bone separate the orbit from the temporal lobe of the brain i the middle cranial fossa. The orbit communicates with the **cranium** by the optic foramen, which transmits the optic nerve and ophthalmic **artery** and by th superior orbital fissure through which pass all the other vessels and nerves of th orbit.

In cases of fracture of the base of the skull involving the anterior clinoid process, a traumati communication (arteriovenous aneurysm) may be formed between the internal carotid arter and cavernous sinus, behind the apex of the orbit, giving rise to pulsating exophthalmos.

The **orbital margin** is larger in the transverse than in the vertical direction and consequently there is more space on either side than above and below be tween it and the eyeball, which is nearly spherical. The eyeball lies nearer to th medial than to the lateral margin and hence foreign bodies more commonly penetrate the orbit to the lateral side of the eye.

Behind the **fascia bulbi**, the eyeball rests on a mass of **soft loose orbital fa** (figs. 847, 848) in which foreign bodies may be hidden for a considerable time.

The structure of the eyelids.—The different layers (**fig. 1081**) are of mucl practical importance. (1) The **skin** is delicate and fatless, and contains pigment the object of this being to protect the eye from bright light. It helps to explai the 'dark circles' of later life. (2) **Subcutaneous areolar tissue.** Owing to its looseness and delicacy, this is very liable to infiltration, as in **edema and erysipelas**

(3) **Orbicularis oculi.** Paralysis of this, the palpebral portion, leads to epiphora, the puncta being no longer kept in their normal backward direction against the conjunctiva. (4) **Palpebral fascia,** reaching from the orbit to the tarsal cartilage. This is usually strong enough to prevent hemorrhage, due to fractured base of skull, becoming subcutaneous. (5) **Levator palpebræ.** (6) **Tarsal plate,** consisting of densely felted fibrous tissue. (7) **Tarsal** (Meibomian) **glands, lashes, and sebaceous follicles.**

Localized inflammation starting in any of these last three structures, especially the last, will cause a 'stye.' The frequency with which the lid-border is the seat of that most troublesome chronic inflammation, blepharitis, and its result, 'blear eye,' is explained by these anatomical points. Its circulation is terminal and slow; half skin and half mucous membrane, it is moister and more liable to local irritation than the skin; while its numerous glands readily participate in any inflammation.

(8) **The conjunctiva.** To trace this important membrane, the lids should be everted, when the following will be noted. The conjunctiva over the tarsal part of the lid is closely adherent, and through it a series of nearly straight, parallel, light yellow lines and granules, the tarsal glands, can be seen. Owing to their position here (fig. 1081) and to avoid scarring, a tarsal cyst is always opened on its conjunctival surface.

Beyond the tarsi, the palpebral conjunctiva is thicker and freely movable owing to the abundant lax submucous tissue. Underlying vessels are visible here. Leaving the eyelid the conjunctiva is reflected onto the eyeball at the **fornix** (cf. fig. 845). Into the lateral part of the upper fornix open the ducts of the lacrimal gland (fig. 854). The bulbar conjunctiva is continued over the front of the eyeball to the corneal margin. It is thin and contains fine vessels which are distinguished from subjacent episcleral vessels by the fact that they move with the conjunctiva.

These **conjunctival vessels**, derived from the lacrimal and palpebral arteries, become easi visible in conjunctivitis. In deep inflammation affecting the iris and ciliary body, the episcle branches of the anterior ciliary arteries (which are derived from the muscular and lacrim arteries) become engorged and are visible as a pink circumcorneal zone of congestion, deep situated under the conjunctiva. These branches take a large share in the nutrition of the corne and are responsible for the vascularity of *pannus* and the '*salmon-patches*' of interstitial kerati

The **conjunctival nerves** for the upper lid and bulbar part of the membrane, and the nerv to the cornea, are supplied by the ophthalmic division of the trigeminal. The maxillary di sion of this nerve supplies the lower palpebral conjunctiva.

The differing structure of the palpebral and ocular portions has important bearings. Th the palpebral conjunctiva is thick, highly vascular and sensitive. To this vascularity we ow the chemosis, or hot, red, tense swelling of purulent ophthalmia. The exquisite suffering the same disease, or that caused by a foreign body, is explained by the numerous nerve-papill and end-bulbs. To the thickness and abundance of the connective tissue are due the contra tion and permanent thickening which may occur in granular lids. The so-called granulation met with in this disease on the palpebral conjunctiva, are really little nodules of hypertrophie lymphoid follicles, or mucous glands, which abound here.

FIG. 1082.—THE LACRIMAL APPARATUS AND NASOLACRIMAL DUCT. (Bellamy.)
(Bristles are introduced into the puncta lacrimalia.)

Immediately under the bulbar conjunctiva, between it and the sclerotic, lies the anterior part of the **fascia bulbi** (of Tenon). This fibrous membrane forms a sheath for the posterior five-sixths of the eyeball, and is intimately connected with the sheaths of the extrinsic muscles and through the **check ligaments** with the orbital walls (figs. 847, 848). Together with the conjunctiva it must be opened in the operation of tenotomy for strabismus, and after division of a rectus tendon the muscle retains some control over the eye through its connection with the fascia bulbi. In enucleation of the eyeball both conjunctiva and fascia bulbi are divided around the cornea, where they are intimately blended. In removal of the upper jaw the attachment of the suspensory ligament of this fascia must always be left if possible, for otherwise the eyeball will tend to fall forward and the cornea suffer from its exposure (Lockwood). Finally the cavity between the two layers of the capsule is continuous with the extensions of the cere bral membranes along the optic nerve, i. e., with the subarachnoid space.

For an account of the intrinsic and extrinsic muscles of the eye the reader is referred to the section on the EYE. Reference may be made here, however, to the part played by certain fiber of the **cervical sympathetic** system (cf. fig. 744). Emerging from the cord at the first and second thoracic segments, the communicating fibers pass up the sympathetic chain in the neck to cell-stations in the superior cervical ganglion. Thence continuing onward through the caro tid canal and superior orbital fissure, they supply (1) the dilator muscle of the iris, (2) the un striped muscle element in the eyelids, and (3) smooth muscle-fibers, described by Sappey in the check ligaments and fascia bulbi. Paralysis of the cervical sympathetic nerve in the neck, usually in its lowest part, by trauma or the pressure of a malignant growth, causes there fore (1) narrowing of the pupil, (2) narrowing of the palpebral fissure (pseudoptosis), and (3 enophthalmos. These symptoms may be observed in fractures of the spinal column involving the lower cervical vertebræ.

The **lacrimal gland** lies in a hollow at the superolateral angle of the orbit protected by the zygomatic process of the frontal bone. It is not palpable nor mally. Its lower or palpebral portion rests on the lateral third of the fornix

conjunctiva, into which the numerous ducts open, and it may be seen through the conjunctiva on everting and raising the upper lid.

The **position of the lacrimal puncta** should be noted; owing to their backward direction, the lids must be previously everted. The puncta are kept open by a minute fibrous ring.

Each is situated on a minute papilla. Close to the medial angle, in addition to the puncta and papilla, should be noted the caruncula lacrimalis, with its delicate hairs, and the plica semilunaris, which corresponds to the third eyelid of certain birds.

The **lacrimal sac** is a most important part of the lacrimal apparatus, from its disfiguring diseases; it lies in a bony groove, between the nasal process of the maxilla and the lacrimal bone. The medial palpebral ligament crosses it a little above its center (figs. 854, 1082). Thus two-thirds of the sac are below the ligament, and in suppuration the opening is made below it also. The angular artery ascends on the nasal side of the sac.

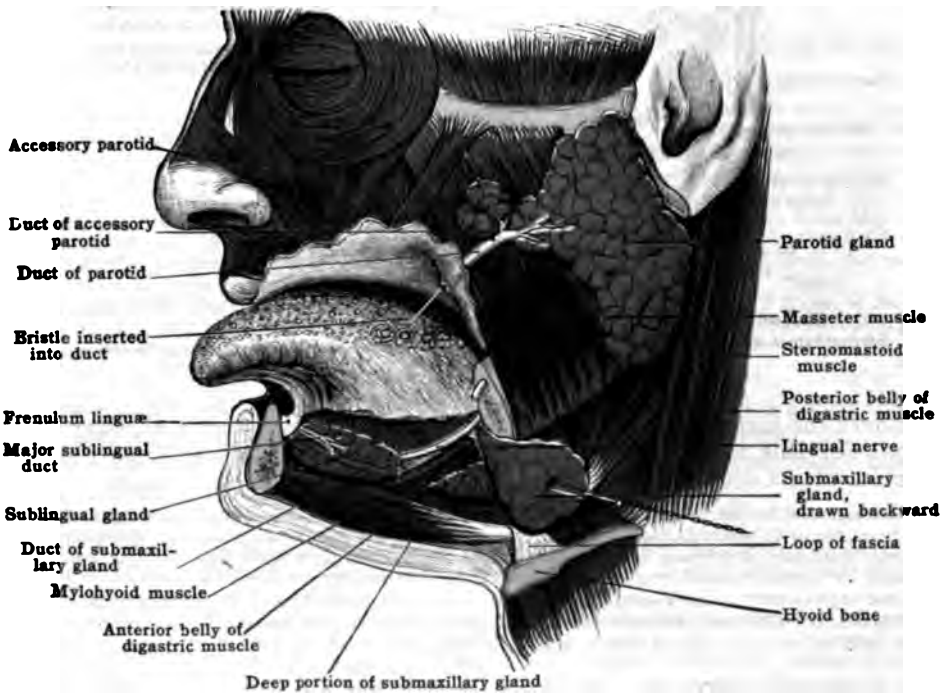
The **manipulation of a probe along the lacrimal passages** should thus be practised:—the lower lid being drawn laterally and downward by the thumb, the probe is passed vertically into the punctum, then turned horizontally and passed on till it reaches the medial wall of the sac. It is then rotated somewhat forward, raised vertically, and pushed gently along the duct downward, and a little lateralward and backward, till the floor of the nose is reached, the operator aiming, as it were, for the site of the first molar tooth. The *nasolacrimal duct* extends from the lower end of the lacrimal sac to the inferior meatus of the nose and is about 1.2 cm. (½ in.) in length.

If the eyes are opened naturally, the greatest part of the cornea, behind it the iris, with the pupil in the center, on either side of the cornea some of the sclerotic, the semilunar fold, and caruncle can be seen. For further details, see section on the EYE.

THE MOUTH

The lips.—When the whole thickness of the lip is incised the labial artery will be found lying near the free margin, internal to the orbicularis muscle, and

FIG. 1083.—SIDE OF THE FACE AND MOUTH CAVITY, SHOWING THE THREE SALIVARY GLANDS.



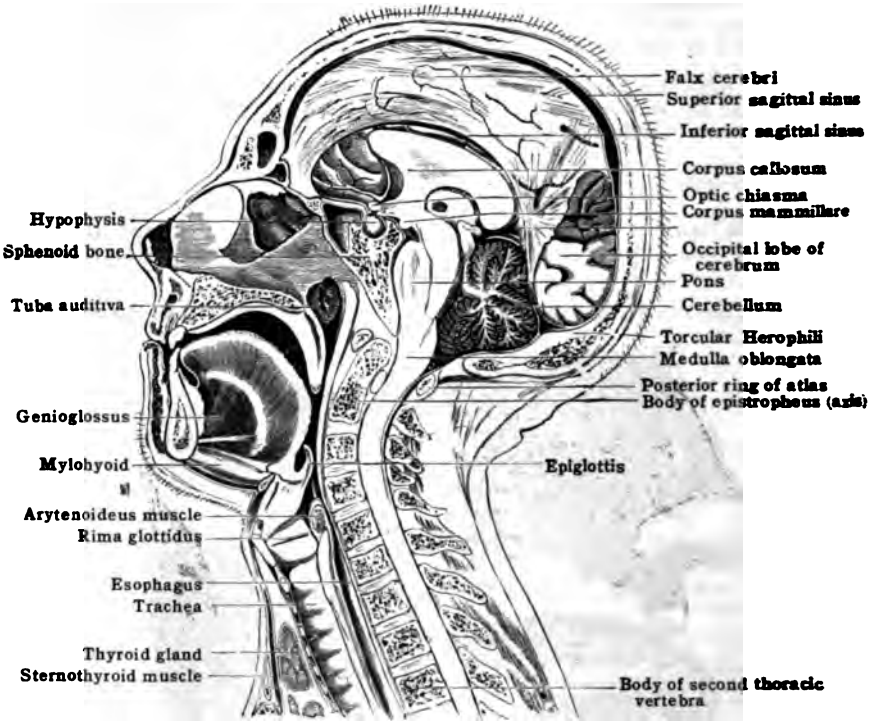
between it and the mucosa. There is a very free anastomosis between the arteries of the opposite sides.

If the tongue be raised, the under surface is seen to be smooth and devoid of papillæ. In the middle line is the **frenulum** (figs. 884, 1083). When division of this is really required (which is not often) in tongue-tie, the scissors should be kept close to the bone, in order to avoid the ranine vessels.

Of these, the veins can be seen just to one side; the arteries are close by, but deeper. Farther out are two more or less distinct fringed folds, the plicæ fimbriatæ, running from behind forward and, like the frenulum, disappearing before the tip. Between these and the frenulum are the small apical mucous glands of Nuhn or Blandin. A retention cyst of this gland is called a ranula, as it resembles a frog's belly in the floor of the mouth. Further back, at the junction of the mucous membrane and the alveoli, are two other projections of the mucosa, the sublingual; under these are the sublingual glands, the ranine veins, and, more deeply, Wharton's duct (in which salivary calculi are occasionally found) and the termination of the lingual nerve. The majority of the ducts of the sublingual gland (Rivinian) open on the sublingual ridges. A single larger one, Bartholin's, opens with that of Wharton, or close to it, on either side of the frenulum (fig. 1083).

The **submaxillary gland** can be felt nearer the angle of the jaw, lying between its fossa and the mucous membrane, especially if pressure is made from outside. The attachment of the **genioglossi** can be felt behind the symphysis: the division of the muscles allows the **tongue** to come well out of the mouth; but when both have to be divided, the tongue loses much of its steadiness, and may easily fall

FIG. 1084.—MIDSAGITTAL SECTION OF THE HEAD AND NECK. (Braune.)



back over the larynx during the administration of the anesthetic or, later on, in sleep. For this reason, in removal of one-half of the mandible, part of this muscular attachment should always be left, if possible.

Turning now to the dorsum of the tongue (figs. 889, 1083), this shows two distinct parts: one, the anterior two-thirds, *the buccal*, is rich in papillæ; the other, the posterior, the *pharyngeal*, contains abundant lymphoid follicles like the tonsil. This part possesses peculiar sensibility, as shown by movements of tongue and palate when a depressor is placed too far back. The two parts are separated by the V-shaped arrangement of the vallate papillæ, with the apex turned backward. Immediately behind the apical vallate papilla is a small pit, the foramen cecum which represents the upper remains of the thyroglossal tract, and may be the seat of lingual thyroid growths. While the tongue is mainly a muscular organ, the fine fatty connective tissue in the septum and between the muscular bundles is the seat of that dangerous condition, acute glossitis, and of gummatous infiltration. While the mouth is widely open, the pterygo-mandibular ligament can be seen and felt beneath the mucous membrane, behind the last molar tooth. Just below and in front of the lower attachment of this ligament the lingual nerve can be felt lying close to the bone below the last molar. The simplest and surest method of dividing the nerve here, to give relief from pain in incurable carcinoma of the tongue, is to draw the tongue out of the mouth and expose the nerve where it lies superficially under the mucous membrane thus made prominent between the side of the tongue and the gums, the center of the incision being opposite to the last molar tooth. (Roser, Létiévant.) In cancer of the tongue pain is often referred up the auriculotemporal nerve to the ear and side of head.

Behind the last molar tooth can be felt the **coronoid process,** and higher up, just behind and medial to the tooth, the **pterygoid hamulus of the sphenoid.** This process is a landmark to the site of the greater palatine foramen, which lies just in front of it, and which transmits the greater palatine branch of the descending palatine artery, together with the anterior palatine nerve. The vessel and nerve run forward in grooves on the lower surface of the palatine process of the maxilla, giving off anastomosing branches toward the middle line, and join at the incisive foramen with the nasopalatine artery.

Their position must be remembered in raising the flaps during the operation for closure of a cleft in the hard palate. To ensure the vitality of the flaps the incisions must be made lateral to the vascular arch, close to and parallel with the upper alveolus, and should not extend beyond a point opposite to and just medial to the last molar tooth, for fear of encroaching upon the posterior palatine canal.

When the teeth are clenched, there is still a space, communicating between the mouth and pharynx behind the molar teeth, which admits a medium-sized catheter. When a patient breathes deeply through the mouth and the head is thrown back, the soft palate is raised, the arches (pillars) separated; the uvula and fauces, with the anterior and posterior palatine arches, with their attachments, the tonsils, and the back of the pharynx are exposed.

This portion of the pharyngeal mucous membrane would lie over the lower part of the second and the upper part of the third cervical vertebra, the anterior arch of the atlas corresponding to the level of the posterior nares, and the body of the epistropheus (axis) to the level of the soft palate (fig. 1084). If finger be introduced past the soft palate to this part of the spine and turned upward and downward, it is possible, with the aid of an anesthetic, to examine the upper four or five and, in children, six vertebræ, as far as the anterior surfaces of their bodies. The part of the column which is accessible to a straight instrument introduced through the mouth is very limited, extending, in the adult, from the lower border of the axis to the middle or lower part of the fourth cervical vertebra; in the child, owing to the small size of the face, it comprises the bodies of the axis and of the third cervical vertebra.' (Thane and Godlee, from Chipault.) The distance from the incisor teeth to the commencement of the esophagus at the cricoid cartilage is 15 cm. (6 in.) in the adult, and the distance from the teeth to the cardiac orifice of the stomach is 48 to 50 cm. (16 or 17 in.)

The *lymphatic drainage* of the face, mouth, and tongue is given on pp. 744 and 749.

The finger may be introduced through the mouth into the pharynx, especially if the parts are rendered insensitive by local anesthetics. Inferiorly may be felt the root of the tongue, the epiglottis and the arytenoepiglottideon folds. If if the finger be turned upward into the nasal pharynx and then forward, it will feel the choanæ (posterior nares), separated by the vomer. The other boundaries of these are, laterally, the medial pterygoid plate and palate bones; above, the basisphenoid; and below, the horizontal plate of the palate bone and the inferior nasal spine. Within each nostril would be felt the posterior ends of the two lower nasal conchæ (turbinate bones); above and behind is felt the basilar process of the skull, the vault of the pharynx, and the bodies of the upper cervical vertebra (fig. 1084).

The **size of the choanæ,** in the bony skull 2.5 cm. (1 in.) vertically by 1.2 cm. (½ in.), and the presence of any adenoids, are especially to be noted. The **richness of the nasopharynx in glandular structures,** its proneness to inflammation, and of this inflammation to spead to other parts,—e. g., the tympanum,—are well known.

The palate.—Between the diverging anterior or glossopalatine arches (pillars) of the soft palate is the **isthmus faucium,** through which the mouth opens into the oral pharynx. It is bounded above by the free margin of the palate and the uvula, laterally by the anterior (glossopalatine) arches, and below by the dorsum of the tongue. The coverings of the hard palate are chiefly mucous membrane, glands, and periosteum. These are intimately blended by fibrous septa, as in the superficial layers of scalp and palm of the hand. Hence the readiness with which necrosis takes place here.

Hare-lip and cleft palate.—Failure of union between the medial nasal process and the maxillary process of the embryo gives rise to the deformity known as **hare-lip** (cf. p. 1138).

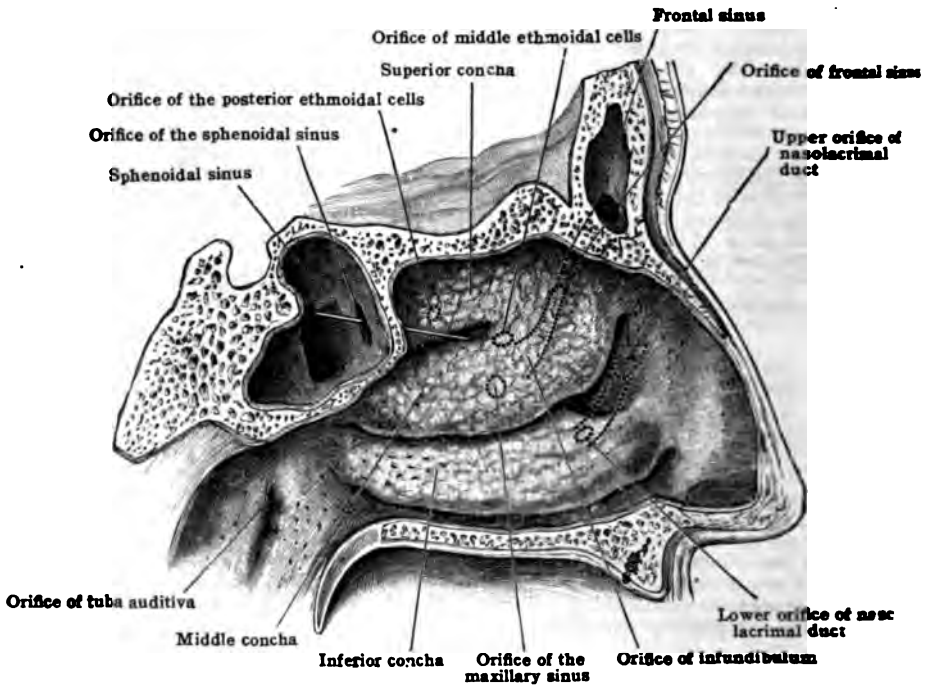
The palate is developed from three primitive processes growing down from the basis cranii, viz., (1) the medial nasal process forming the premaxilla which lies in front of the anterior palatine foramen and bears the four incisor teeth, (2) and (3) the maxillary process of either side. The slighter cases of failure to unite affect only the soft palate which is the last part to fuse. Complete alveolar cleft palate, which occurs combined with hare-lip and may be unilateral or bilateral, represents more serious non-union. In this condition the lateral incisor may be found either on the medial or on the lateral side of the cleft, which is explained by the fact that this tooth is developed in the groove between the two processes (Keith).

In paring the edges of a cleft soft palate, the following structures would be successively cut through:—(1) Oral mucous membrane; (2) submucous tissue, with vessels, nerves, and glands; (3) glossopalatine muscle; (4) aponeurosis of tensor palati; (5) anterior fasciculus of pharyngopalatine; (6) levator palati and uvular muscles; (7) posterior fasciculus of pharyngopalatine; (8) submucous tissue, vessels, nerves, and glands; (9) posterior mucous membrane. The soft palate is thicker than it seems, the average in an adult being 6 mm. (¼ in.). The muscles widening a cleft are the tensor and levator, while the superior constrictor closes it in swallowing. Of the *arteries* of the palate, from the external maxillary (facial), ascending pharyngeal, and internal maxillary, the largest is the descending palatine branch of the last. This emerges from the posterior palatine canal close to the medial side of the last molar tooth.

THE NOSE AND PHARYNX

On the face the outline of the nasal bones can be easily traced, and below them the lateral nasal cartilages, flat and also somewhat triangular. Below these are the greater alar cartilages, curved and so folded back that each forms a lateral and a medial plate. Of these, the medial meet below the septal cartilage to form the tip of the nose, while the lateral curve backward, and, together with dense masses of cellular tissue and fat and accessory cartilages, form the ala.

FIG. 1085.—SECTION OF THE NOSE, SHOWING THE CONCHÆ (TURBINATES) AND MEATUSES WITH THE OPENINGS IN DOTTED OUTLINE.



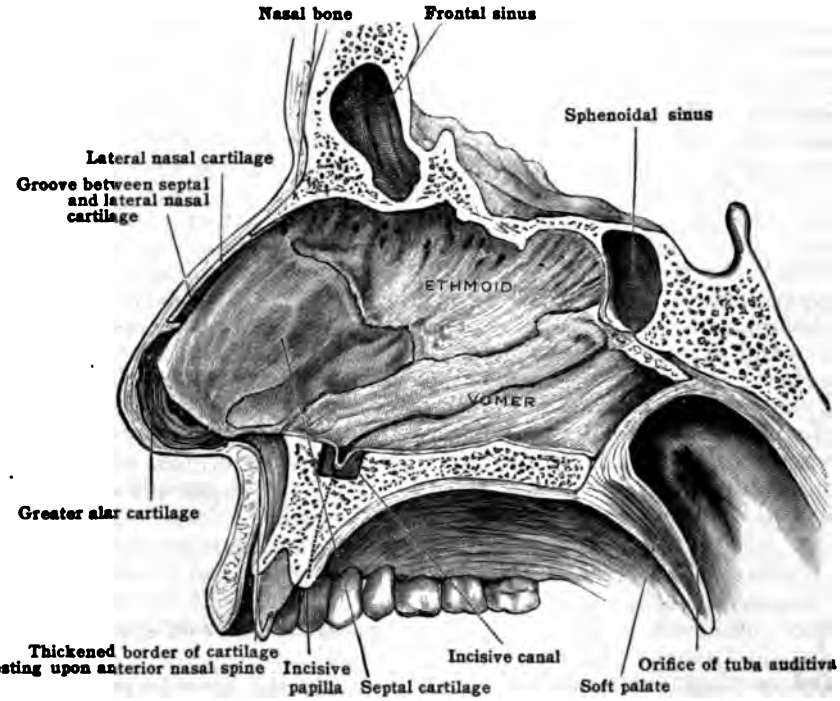
With the speculum, especially if the head be thrown back and the tip of the nose drawn up, the lower part of the septum, floor of the nose, and greater portion of the inferior concha (turbinate) can be seen. On throwing the head further back, with a good light the lower margin of the middle concha can also be made out. This is much higher up and nearly on a level with the root of the nasal bone. The septum often deviates to one side. The mucous membrane over it is, in health, dull red in color; that over the inferior concha is thicker. The anterior extremity of the latter bone is about 1.8 cm. (¾ in.) behind the nasal orifice, while the opening of the nasolacrimal duct is about 2.5 cm. (1 in.) behind and about 1.8 cm. (¾ in.) above the floor, concealed by the anterior extremity of the inferior concha. The opening into the maxillary sinus (antrum) is situated in about the center of the middle meatus and 2.5 cm. (1 in.) above the floor.

The olfactory area of the mucous membrane extends over the highest conchæ (possibly also somewhat lower) and corresponding portions of the septum. The respiratory portion is more vascular and thicker, especially over the conchæ. It is firmly adherent to the periosteum and perichondrium. The veins, especially

over the lower concha, form a dense plexus, closely resembling cavernous tissue. This fact explains the severity of epistaxis, and, together with the drainage of blood into out-of-the-way veins, such as the sphenopalatine and ethmoidal, accounts for the serious results which may follow on a firmly impacted and infected plug. The boundaries of the choana (posterior nares) have been given above.

Nasal septum.—The structure of the skeletal element of the septum, which consists of the septal cartilage, the vertical plate of the ethmoid and the vomer, is shown in fig. 1086. Slight deviations of the septum to one side are common in adults, and involve mainly the cartilage and the ethmoid bone, the vomer being but little affected as a rule.

FIG. 1086.—SECTION SHOWING BONY AND CARTILAGINOUS SEPTUM.
The dotted line indicates the course of the incisive (anterior palatine) canal.



The convexity is most commonly on the right side, and occlusion of the nares on that side with unsightly deflection of the whole nose, results in some cases during the transition from the infantile to the adult facial conformation. Too extensive removal of the bony septum in the operation of submucous resection for the relief of this condition may cause sinking in of the bridge of the nose. More often, however, this is due to the destructive effect of congenital syphilis.

Accessory sinuses.—The communications of these paranasal air sinuses with the nasal fossa are of great clinical importance. The **sphenoidal sinus** opens high up into the sphenoethmoidal recess. **The posterior ethmoidal sinuses** open into the superior meatus under cover of the superior concha. The infundibulum of the **frontal sinus, the anterior** and **middle ethmoidal** and the **maxillary sinus** all communicate with the middle meatus under cover of the middle concha. The orifice of the **maxillary sinus** lies at the lowest part of the hiatus semilunaris into the front and upper end of which the frontal sinus opens. Consequently infected fluid may trickle down from the latter into the maxillary sinus. The orifice of this sinus is placed high up in its medial wall so that fluid does not drain away from it readily in case of infection. When the head is held forward in a stooping position some of the pus or mucus may escape from the nostrils, since in this position the fluid contents more readily reach the orifice. For further details concerning the sinuses, see RESPIRATORY SYSTEM.

The **nasolacrimal duct** which carries the tears into the nose opens into the front and upper part of the inferior meatus under cover of the inferior concha.

Nasopharynx.—About 1.2 cm. (½ in.) behind the posterior extremities of the inferior conchæ, just above the level of the hard palate (fig. 1048), on the side of the nasopharynx, are the openings of the *tubæ auditivæ* (**Eustachian tubes**). Oval in shape, these are bounded above and behind by the prominence of the cartilage [torus tubarius], which is wanting below, thus facilitating the entry of a catheter. The lower part of the tube contains in early life lymphoid tissue; enlargement of this explains the deafness in certain cases of adenoids. At the upper part of the nasopharynx, on the posterior wall, extending down laterally as far as the tubæ auditivæ, is the collection of lymphoid tissue known as the **pharyngeal tonsil,** which when hypertrophied, plays a large part in 'nasopharyngeal adenoids.' From the periosteum of the basisphenoid and basioccipital arise nasopharyngeal fibromata. For digital exploration of the pharynx through the mouth, see p. 1351.

Pharyngeal hypophysis (fig. 1069).—In the nasopharyngeal mucosa, a few mm. behind the posterior border of the vomer, a group of glandular cells may be found on microscopical examination in all cases (Haberfeld), corresponding in histological appearance with the pars anterior of the hypophysis. These cells are a remnant of the primitive bud that grows toward the brain in front of the buccopharyngeal membrane to form the pars anterior of the hypophysis. In some cases of pituitary disorder they give rise to a palpable tumor in the nasopharynx.

Oral pharynx.—The **palatine tonsils** are located in the side walls of the oral pharynx (figs. 880, 889). They are separated externally by the superior constrictor and pharyngeal aponeurosis from the ascending pharyngeal and internal carotid arteries. The latter vessel lies about 2.5 cm. (1 in.) behind and to the lateral side of the tonsil. When serious hemorrhage follows operations here, it usually comes from one of the numerous tonsillar branches (fig. 492). The extent to which the tonsil is covered by the anterior arch (pillar), how far it projects upward beneath the soft palate or downward into the pharynx, have all important bearings on the mode of removal. Its position corresponds to a point a little above and in front of the angle of the jaw. The lateral surface, enclosed by an imperfect capsule and separated from the superior constrictor by connective tissue, explains how an enlarged tonsil can be dragged medialward by a vulsellum, and enucleated after an incision in the mucous membrane around. It is in this connective tissue that severe infective inflammation, e.g., after scarlet fever or an imbedded pipe-stem, may set up hemorrhage or spreading cellulitis, retropharyngeal or otherwise.

THE NECK

The topics considered in the neck are the landmarks, thyroid gland, sternomastoid, clavicle, triangles and cervical ribs.

Bony and cartilaginous landmarks.—The body of the *hyoid* is nearly on a level with the angles of the jaw, and the interval between the third and fourth cervical vertebræ (fig. 1084). With the head in the usual erect position it lies a little higher than the chin. It divides the front of the neck into supra- and infrahyoid regions, convenient for remembering the distribution of the deep fascia. On either side of the body are the greater cornua, with the lesser cornua attached to their upper borders at the junction with the body. The upper borders of these are the guides to the lingual arteries. The outline and mobility of the body and the greater cornua are easily determined by relaxing the deep fascia and pushing the bone over to the opposite side. Below the hyoid is the *thyrohyoid space*, which corresponds with the epiglottis and the upper aperture of the larynx. Thus, if the throat be cut above the hyoid, the mouth will be opened and the tongue cut into; if the thyrohyoid space be cut, the pharynx would be opened and the epiglottis wounded near its base. In the former case the lingual and external maxillary are the most likely vessels to be wounded; in thyrohyoid, the commonest cut-throat, the superior thyroid vessels, and the superior laryngeal nerve. The *laryngeal prominence* and thyroid notch begin about 2.5 cm. (1 in.) below the hyoid and are much more distinct in men than in women or children. The prominence is not marked before puberty, and thus forms a less distinct landmark for tracheotomy, especially in children with short fat necks.

The cricoid, on the other hand, is always to be made out. It corresponds in horizontal plane to the following: (1) The sixth cervical vertebra, (2) The junction of pharynx and œsophagus: from the narrowing of the tube here, foreign bodies may lodge at this point and cause dyspnœa by pressing on the air-tube in front. The cricoid is taken as the center of the incision

in esophagotomy, and also for ligature of the common carotid. (3) The junction of larynx and trachea. (4) The crossing of the omohyoid over the common carotid. (5) The middle cervical ganglion. Above the cricoid is the cricothyroid membrane. In laryngotomy, the deepest part of the incision should be kept to the middle line for fear of injuring the cricothyroids, and as near the cricoid as possible, so as to avoid the neighborhood of the vocal folds (cords) and the small cricothyroid vessels. The space is always small, and, after middle life, increasingly rigid.

The distance between the cricoid and the manubrium is only about 3.7 cm. (1½ in.). When the neck is stretched, about 1.8 cm. (¾ in.) more is gained. Thus, as a rule, there are not more than seven or eight tracheal rings above the sternum. Of these, the second, third, and fourth are covered by the isthmus of the thyroid gland.

The parts met with in the midline—(*a*) above, and (*b*) below, the isthmus—high and low tracheotomy—should be borne in mind: (*a*) Skin, superficial fascia, branches of transverse cervical and inframandibular nerves, lymphatics, cutaneous arteries, anterior jugular veins—with their transverse branches smaller above—deep fascia, sternohyoids, cellular tissue, superior thyroid vessels, and pretracheal layer of deep fascia. The importance of this last is twofold, as, first, the tube in tracheotomy may be passed between it and the trachea, and after a wound in this region this layer, continuous with the pericardium, may conduct discharges, into the mediastina. (*b*) The surface structures are much the same, but the anterior jugular veins and their transverse branches are much larger. The inferior thyroid veins, are also larger. A thyroidea ima may be present, and the innominate artery, especially in children, may be 1.2 cm. (½ in.) above the sternum. The trachea is also smaller, deeper, and less steadied by muscles. The *thymus*, too, in young children (fig. 1087), may prove a difficulty. Thus, in children, the high operation, incising the cricoid and cricotracheal membrane, if needful, is to be preferred. The cricoid is, however, not to be incised, if possible; the higher the tube is inserted, the greater the irritation.

The suprasternal notch, between the sternal heads of the sternomastoids in on a level with the disk between the second and third thoracic vertebræ. Just below the level of the cricoid cartllage, on deep pressure at the anterior border of the sternomastoid the transverse process of the sixth cervical vertebra may be felt. It is known as Chassaignac's carotid tubercle, and the common carotid may be compressed against it. Compression below it will command the vertebral artery as well.

The **thyroid gland** (figs. 1052–1056) enclosed in a capsule of deep fascia derived from the pretracheal layer (fig. 1054) is closely connected by this to the upper trachea and larynx. The upper somewhat pointed extremity of each lateral lobe reaches to the upper and back part of the thyroid cartilage: here enter the superior thyroid vessels. The lower layer and rounded extremity reaches to the fifth or sixth tracheal ring: its posterior and lower aspect is in relation to the inferior thyroid vessels and the recurrent nerve: the lateral lobe, posteriorly, also overlaps the carotid sheath, which may be infiltrated in malignant disease of the thyroid. The thyroidea ima has been mentioned above.

The thyroid isthmus in the adult is opposite to the second, third, and fourth tracheal rings. At its upper border is an arterial arch formed by the superior thyroids; over the anterior surface of the gland and isthmus the inferior thyroid veins take origin in a plexus. The upper border of the thymus (fig. 1087) may be in relation with the lower border of the isthmus. From the upper border of the latter, the pyramidal lobe, especially on the left side, is often present, reaching by a pedicle to the hyoid. The pyramidal lobe, when present, is the persistent remnant of the thyroglossal duct, and occasionally cystic outgrowths persist obstinately as remnants of this duct, in the middle line, above, behind, and below (the commonest form) the hyoid bone.

In short-necked people the thyroid is relatively lower in relation to the sternum, and enlargements of the gland are apt to become mainly intrathoracic. The presence of an intrathoracic or retrosternal goiter may be determined by X-ray examination. An enlargement of the thyroid is liable to give trouble by pressure on (1) the trachea, which is compressed laterally between the lateral lobes; (2) the esophagus; (3) the internal jugular vein and carotid artery; (4) the recurrent laryngeal or cervical sympathetic nerves.

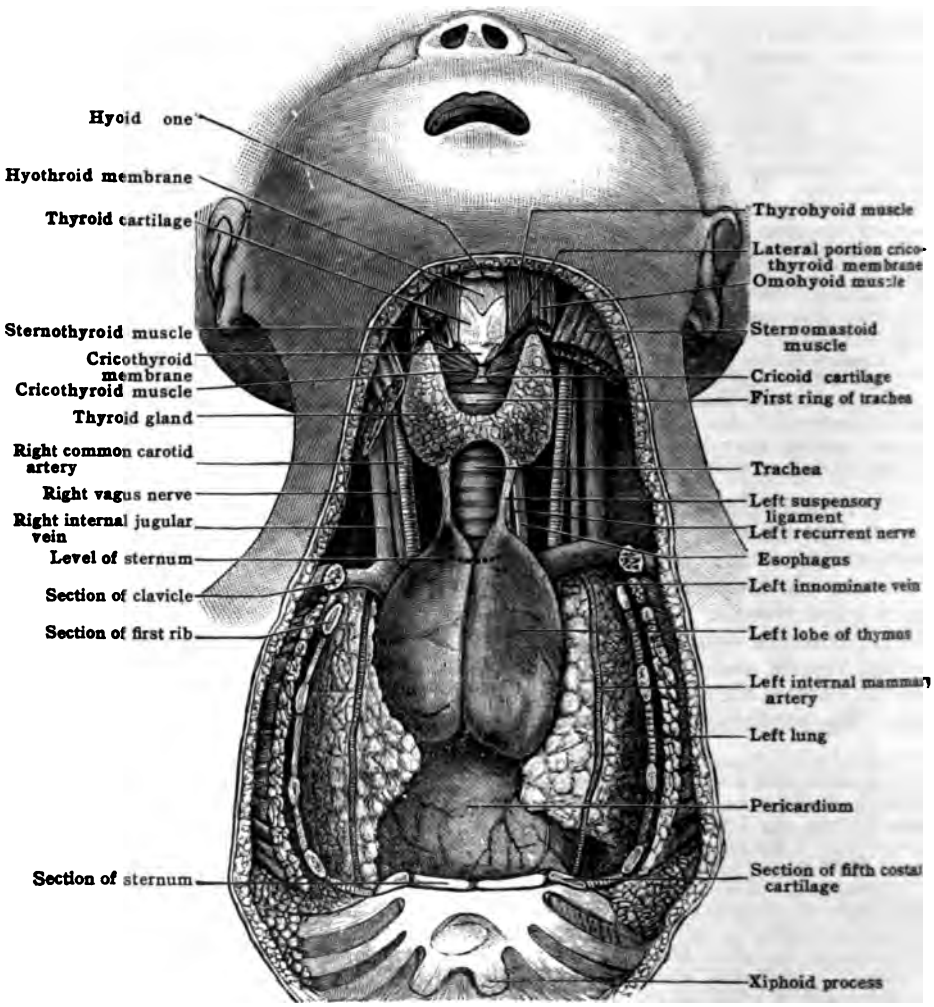
Parathyroids.—These small glands, about the size of a pea, vary somewhat in number and situation (fig. 1057). There are usually four—two behind each lateral lobe. The upper glands lie imbedded in the capsule of the thyroid about the junction of the middle and upper thirds of the lateral lobes on the posterior aspect. The lower pair lie nearer the lower poles of the lateral lobes, sometimes separated from them by a distinct interval. Excision of all the parathyroids gives rise to tetany in animals.

The **sternomastoid** (figs. 1079, 1088) is the landmark for several important operations. Its medial border, the thicker and better marked of the two, overlaps the carotids: the common carotid corresponding, as far as the upper border of the thyroid cartilage, with a line drawn from the sternoclavicular joint to midway between the mastoid process and the angle of the jaw. The artery can be best compressed above the level of the cricoid, as here it is less deeply covered. The student should recall the deep relations of the sternomastoid, which he may

classify as vessels, nerves, muscles, glands, and bones: or, according to their position, (1) those above the level of the angle of the jaw: (2) those between the angle of the jaw and the omohyoid: (3) those below the omohyoid.

Of the two heads of the sternomastoid the sternal is the thicker and more prominent, the clavicular the wider. A stab through the interval which lies between the two heads might wound the bifurcation of the innominate on the right side, and the common carotid on the left, the internal jugular vein, vagus, and phrenic nerves, according to the direction of the wound. Injury of the sternomastoid during child-birth, followed by scar-tissue formation, may give rise to wry-neck.

FIG. 1087.—THYMUS AND THYROID GLAND IN A CHILD AT BIRTH.



The anterior jugular vein (fig. 552), commencing in branches from the submaxillary and submental regions, descends at first in the superficial fascia between the midline and anterior border of sternomastoid, perforates the deep fascia just above the clavicle, here entering Burns's space (p. 1362): it then curves laterally to pass beneath both origins of the sternomastoid a little above the clavicle, to end usually in the external jugular.

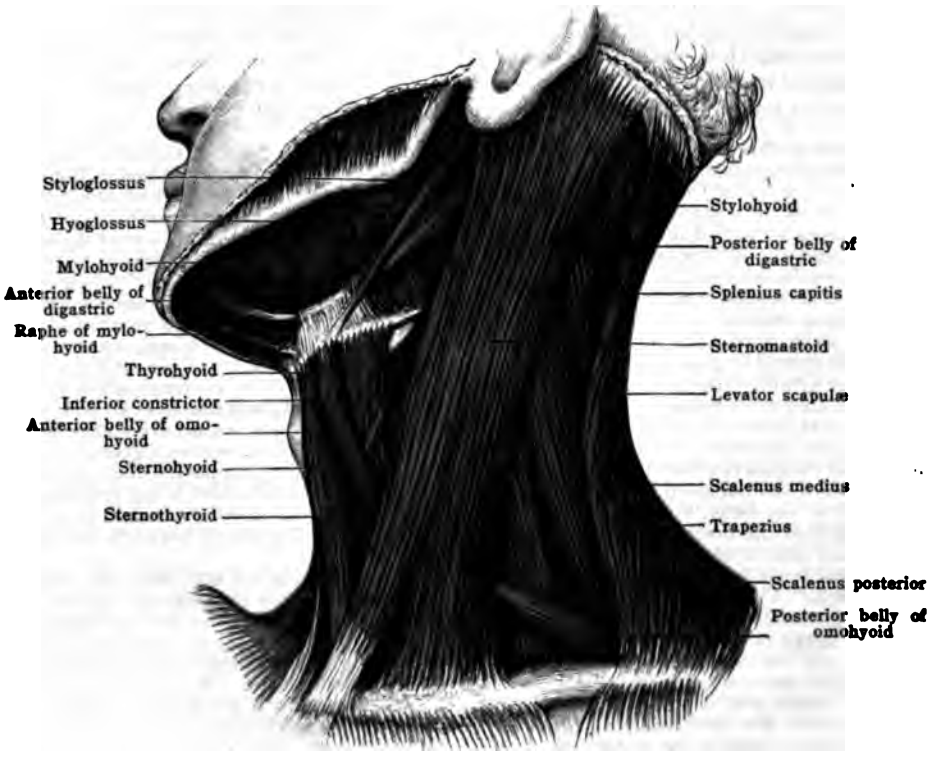
When distended, a large communicating branch between it and the common facial, which runs along the anterior border of the sternomastoid, must always be remembered in operations for removal of glands, etc. The varying level at which the external jugular crosses the lateral border of the clavicular origin must be remembered in such operations as tenotomy. These veins vary in size inversely to each other; the anterior jugulars are joined by numerous transverse branches and become larger below. They have no valves.

Of the chief arteries to the sternomastoid, that from the superior thyroid will be divided [illegible]rature of the common carotid; that from the occipital runs with the spinal accessory nerve.

Behind the sternoclavicular joint lies the commencement of the innominate veins, the bifurcation of the innominate artery on the right, and the common carotid artery on the left; deeper still lie the pleura and lung.

The clavicle.—This bone can be felt beneath the skin in its whole length. It forms the only bony connection between the upper limbs and the trunk. As one traces it laterally toward the acromial end, it rises somewhat, particularly in children and in subjects of good muscular development. The skin over it is thin but very mobile, and consequently is not often wounded. The most important posterior relations of this bone are, passing from the medial end laterally, the subclavian vein, the subclavian artery, and the cords of the brachial plexus as they lie on the first rib (cf. fig. 562).

FIG. 1088.—ANTERIOR AND LATERAL CERVICAL MUSCLES.



The subclavian vein occupies the angle between the first rib and the clavicle, and hence is, as a rule, the first structure compressed in growths of this bone. The artery lies on a deeper plane behind the midpoint of the clavicle, and the nerve cords extend a little further laterally. The subclavius muscle forms a protective cushion between the bone and these important structures, and this accounts for the rarity of injury to them in fracture of the clavicle. Behind the medial half of the clavicle the apex of the lung extends upward into the neck to a height of 2.5–3.7 cm. (1–1½ in.), and consequently is liable to be wounded by a stab in the root of the neck.

Cervical triangles.—In front of the sternomastoid on each side is the **anterior triangle,** which is **subdivided into three smaller triangles** by the digastric muscle above, and the anterior belly of the omohyoid below (figs. 1079, 1088). These smaller triangles are called, from above, the submaxillary, the superior and inferior carotid triangles. The **submental triangle** is an additional small unpaired area bounded on either side by the anterior belly of the digastric, and posteriorly by the body of the hyoid.

The **submaxillary** or **digastric triangle** is bounded above by the mandible, and a line drawn back to the mastoid process: behind, by the stylohyoid and posterior belly of the digastric, and in front by the anterior belly of the digastric.

This space contains the submaxillary gland, and embedded in the gland is the external maxillary (facial) artery, the facial vein lying superficial to the gland; deeper than the gland are the submental vessels and the mylohyoid vessels and nerve. Posteriorly, and separated from

the above structures by the stylomandibular ligament, which subdivides the triangle into a sub maxillary and parotid part, is the upper part of the external carotid artery running up into the parotid gland, where it gives off its two terminal and the posterior auricular branches. Mor deeply lie the internal jugular vein, internal carotid artery, and the vagus. The floor of th triangle is formed by the mylohyoid, hyoglossus, and superior constrictor. The lingual arter may be tied here, or, better, in order to get behind the dorsalis linguæ, close to its origin, by a incision similar to that for exposing the external carotid. The lingual artery is most easil ligated in Lesser's triangle, which is formed by the *hypoglossal nerve* above and the two belli of the digastric below. The artery is covered by the fibers of the hypoglossus. The hypo glossal nerve is also a guide to the carotids and the occipital artery at the lower border of th digastric.

The **superior carotid triangle** (cf. figs. 488 and 1088) is bounded above by th digastric, below by the omohyoid, and behind by the sternomastoid. It contain the upper part of the common carotid and its branches, the external being at firs somewhat anterior to the internal. The external may be differentiated from th internal carotid by remembering that the latter gives off no branches in the nec All the branches of the external carotid, save the three just given, are found i this space, together with their veins, the internal jugular vein, the vagus an sympathetic nerves, and, for a short distance, the accessory, together wit those nerves which lie in front of and behind the carotids.

Ligature of the common carotid is usually performed at the 'seat of election,' where th vessel is more superficial, *above the omohyoid.* An incision with its center opposite the crico is made 7.5 cm. (3 in.) long in the line of the carotid artery. The deep fascia along the a terior border of the sternomastoid having been divided, the cellular tissue beneath is opened u the omohyoid identified and drawn down or divided. The sternomastoid is next drawn we laterally, and the artery felt for. At this stage, such veins as the communication betwee the common facial and the anterior jugular and the superior and middle thyroids may giv trouble. The sheath is next opened well to the medial side, opposite to the cricoid cartilag the ascending cervical, when seen, being avoided. If the internal jugular be distended, it ma be drawn aside with a blunt hook, or pressure made lightly in the upper angle of the woun The needle should be passed from the lateral side in very close proximity to the lateral and bac part of the artery, as so to avoid the vein and vagus. Ligature *below the omohyoid* is rendere more difficult by the presence of the anterior jugular, the pretracheal muscles, an overlappin thyroid gland, especially if enlarged, the greater depth of the artery, especially on the left sid and, here also, the closeness of the internal jugular. The *collateral circulation* is given at p. 136 Ligature of the external carotid, otherwise difficult, is rendered very simple by first exposing th bifurcation of the common carotid artery, the incision similar to the last being prolonged up ward. Here the facial and lingual veins and hypoglossal nerve cross the trunk, over whic also lie some of the deep cervical glands. The ligature is usually placed between the superi thyroid and lingual branches.

Allusion must here be made to the **chief structures liable to be met with in operation on the neck.** These are the **internal jugular,** the **accessory,** and **phrenic nerves, the vagu** and **hypoglossal,** the **thoracic duct,** low down and deep on the left side, the **esophagus** an **recurrent nerve** in difficult operations on the thyroid gland. Of these, the **internal jugular** i in some ways, the most important. Glands, tuberculous or carcinomatous, are often adherei to its sheath, especially those which drain the submaxillary group. When this condition present or suspected, it is always well to begin the dissection low down in the inferior carot triangle, where the structures are probably normal and the landmarks easy to identify. I infective thrombosis of the transverse sinus the internal jugular is often tied opposite to th cricoid cartilage, being either divided between two ligatures, or, if the thrombus has extende downward, as much of the vein as is possible is removed. This vein contains only a single pa of valves low down in the neck. In all operations here on it and the other two jugulars, th risk of entry of air is to be remembered. The accessory and phrenic nerves are alluded to p. 1360.

The **inferior carotid** (muscular or tracheal) **triangle** is bounded above by th omohyoid, behind by the sternomastoid, and in front by the middle line of th neck (fig. 1088). It contains the lower part of the carotid sheath and its con tents, with, behind it, the inferior laryngeal nerve and inferior thyroid vessel and to the medial side the trachea, thyroid gland, and esophagus. More deepl are the vertebral vessels; on the left side is the thoracic duct.

The position of the **branches of the external carotid (fig. 488) should be r** membered. The greater cornu of the hyoid and the ala of the thyroid are lan marks for the origin of most of them.

The **superior thyroid,** arising just below the level of the great cornu of the hyoid bon passes downward and forward to the back part of the thyroid cartilage and upper part of th thyroid body. Many of its branches are important in surgery. The superior laryng perforates the thyrohyoid membrane. The sternomastoid passes laterally into the midd of the muscle, across the carotid sheath. The cricothyroid crosses the space of the same nam just below the lower border of the thyroid cartilage. The small hyoid branch runs to the low border of the hyoid bone. Anastomosing branches of the superior thyroid form an arch alon the upper border of the isthmus. The lingual artery arises from the parent trunk, opposite th

tip of the greater cornu of the hyoid, and passes forward just above the greater cornu, crossed by the hypoglossal, and thence to the side of the tongue. In the first part of its course, before it reaches the hyoglossus, it is curved, at first ascending, and then, having descended slightly, before it reaches the hyoglossus, and while it lies under it, its curve is gentle, with the concavity upward; beyond the hyoglossus, as it lies on the muscles of the tongue beneath the mucous membrane, it is tortuous. The **lingual vein,** it will be remembered, does not run with its artery, but lies superficial to the hyoglossus. It receives the two small venæ comitantes which run with the lingual itself just before it crosses the common carotid. The line of the **external maxillary (facial) artery** (fig. 1080), which often arises with the lingual, has been given on p. 1343. The **occipital artery;** starting on the same level as the facial (i.e., at a point a little above and outside the tip of the greater cornu of the hyoid bone), follows a line drawn upward and laterally, first to the interval between the transverse process of the atlas and the mastoid process, the former bone being felt just below and in front of the tip of the latter; thence, lying in the occipital groove of the mastoid, the artery ascends gradualy, enters the scalp, together with the great occipital nerve, a little medial to a point midway between the external occipital protuberance and the mastoid process, to follow, tortuously and superficial to the aponeurosis, the line of the lambdoid suture.

The surface marking of the **digastric** and **omohyoid,** which subdivide the anterior triangle into the three smaller subtriangles above described, should be noted. The line of the **posterior belly of the digastric** corresponds to one drawn from the apex of the mastoid process to a point just above the junction of the great cornu and body of the hyoid bone; and from this spot, which gives the point of meeting of the two tendons, one slightly curving upward to a point just behind the symphysis menti, would give that of the **anterior belly.**

To trace the **omohyoid,** a line should be drawn from the lower margin of the side of the hyoid bone obliquely downward, so as to cross the common carotid opposite the cricoid cartilage and thence curving laterally under the sternomastoid at the junction of its middle and lower thirds, and then onward and still laterally parallel with and a little above the clavicle, as far as its center.

Posterior triangle.—This lies behind the sternomastoid (figs. 1079, 1088), bounded posteriorly by the trapezius and inferiorly by the clavicle. It is subdivided by the posterior belly of the omohyoid into a larger, upper *occipital* and a smaller lower *subclavian* triangle. The latter corresponds to a surface depression, the supraclavicular fossa. Here the brachial plexus may be felt, and, by pressure downward and backward immediately behind the clavicle, just lateral to and behind the lateral margin of the sternomastoid, the subclavian artery can be compressed upon the first rib.

The supraclavicular fossa should be opened out by depressing the arm, and parts relaxed by carrying the shoulder forward and turning the head to the same side. The subclavian artery curves upward and laterally from behind the sternoclavicular joint to disappear behind the center of the clavicle, the highest point of the curve being 1.2 to 2.5 cm. (½ to 1 in.) above the bone. The artery on the left side lies more deeply than the right, and does not rise so high into the neck. The subclavian vein lies at a lower level, separated by the scalenus anterior, and under cover of the clavicle. Into the above curve rise the pleura and lung. The pleura may be expected to rise 2.5 cm. (1 in.) above the clavicle, behind the clavicular head of the sternomastoid.

The **transverse scapular** and **transverse cervical vessels** run laterally, parallel with the clavicle. The former lies behind the bone and subclavius; the latter also runs laterally in a transverse direction, across the root of the neck, but on a slightly higher plane, and thus a little above the clavicle. In aneurism of the axillary artery these vessels may form the main part of the collateral circulation and in exposing the subclavian artery for purposes of ligation they should be carefully preserved.

Ligature of the third part of the subclavian is best performed by an angular incision, the horizontal portion along the center of the clavicle, and the vertical one along the posterior border of the sternomastoid, with partial division of this and the trapesius when closely adjacent. The chief points to bear in mind are the venous plexus into which the external jugular, transverse cervical, transverse scapular, and cephalic veins enter; the omohyoid and division of the fascia which ties this to the clavicle; identification of the lateral margin of the scalenus anterior and the scalene tubercle; care of the transverse scapular artery and the descending branch of the transverse cervical. The needle is passed from above downward so as not to include the lowest cord of the brachial plexus, the vein, if distended, being depressed with a blunt hook. If the nerve to the subclavius be seen, it must be uninjured, as it occasionally forms an important part of the phrenic. The *collateral circulation* is given at p. 1360.

Crossing the sternomastoid, a little obliquely, in a line drawn from a point just below and behind the angle of the jaw which marks its origin in the union of the posterior part of the internal maxillary and the posterior auricular veins to the center of the clavicle, runs the **external jugular vein** (fig. 552). Above, it lies between the platysma and deep fascia, and is accompanied by the group of superficial cervical nodes (p. 742). About 3.7 cm. (1½ in.) above the clavicle it perforates the deep cervical fascia, its coats being blended with the opening. Gentle pressure with a finger at this point renders the vein above clearly visible. The dilated part between this point and the subclavian vein is called the sinus, and is marked by two valves, neither of which is usually perfect.

Opening into the external jugular, in the middle or lower third of its course, is the posterior external jugular, a vessel which begins in the occipital region superficially and runs down in front of the anterior border of the trapezius, across the posterior triangle.

The **accessory nerve** (fig. 1079), having crossed the transverse process of the atlas at a point lying a little below and in front of the apex of the mastoid, enters the anterior border of the sternomastoid at about the junction of the upper and middle thirds of the muscle. Having traversed the muscle obliquely, it leaves it usually at a point a little lower down, pursues a similar course across the posterior triangle and disappears under the anterior border of the trapezius, to enter into the subtrapezial plexus with the third and fourth cervical nerves.

Above it is accompanied by a branch from the occipital, below by the transverse cervical artery. It is always seen in thorough operations on the upper deep cervical glands. The nerve is resected in spasmodic torticollis, and in recent years inveterate facial paralysis has been treated by anastomosing the facial to this nerve or the hypoglossal. A line drawn from midway between the tip of the mastoid and the angle of the mandible along the above given course of the nerve would denote its position. The guides for the spinal accessory should be carefully studied. It is not infrequently injured or divided in operations in the posterior triangle of the neck. Division of the nerve may give rise to drop shoulder

Just above the center of the sternomastoid, the **small occipital, great auricular,** and **cutaneous cervical nerves** emerge, the first passing upward and backward to the scalp, the second upward and forward across the upper part of the sternomastoid to the ear, and the last turning straight forward to the front of the neck. The small occipital and great auricular are often in intimate association with the accessory at its exit from the muscle. At this point also care must be taken not to injure the nerve in removal of glands from the posterior triangle.

The **phrenic nerve** (figs. 501, 1091), taking its largest root from the fourth cervical, begins deeply about the level of the hyoid bone: thence descending under the sternomastoid, and, passing obliquely medially across the scalenus anterior (the posterior borders of the above two muscles roughly correspond to each other in the lower part of the neck), it descends under the subclavian vein and clavicle to enter the thorax.

When the internal jugular is distended, its lateral border will be liable to overlap this nerve. The relations of the *scalenus anterior* should be noted here. In addition to the phrenic, which runs with a slight obliquity medially and is in close contact with the muscle, the following structures cross it mediolaterally: the subclavian vein and termination of the external jugular, the transverse scapular and transverse cervical vessels, and the omohyoid. At its medial margin are the thyrocervical trunk and vertebral arteries, and over them, the internal jugular. Behind it are the subclavian artery, the brachial plexus, and pleura.

The level of the **brachial plexus** (upper border) would be given by a line drawn from the cricoid cartilage to the center of the clavicle. The lowest, medial cord (eighth cervical and first thoracic, giving off chiefly the ulnar, medial head of median, and medial antibrachial cutaneous) is just above and behind the subclavian artery. Its importance in ligature of the artery has been referred to (p. 1359).

In paralysis of the newly born, after some violent manipulation, it is usually the upper and lateral cord (fifth nerve, and axillary and median chiefly) which suffers, elevation and abduction at the shoulder and flexion at the elbow-joint being lost. Upper radicular brachial palsy known as Erb's palsy, while palsy arising from injury of the lower roots of the brachial plexus is known as Klumpke's palsy.

Collateral circulation after ligature of the common carotid (fig. 1089).—This takes place by means of (1) the free communication which exists between the opposite carotids, both without and within the cranium; and (2) by enlargement of the branches of the subclavian artery on the same side as that on which the carotid has been tied. Thus, outside the cranium, the superior and inferior thyroids are the chief vessels employed. Within the cranium the vertebral replaces the internal carotid.

Collateral circulation after ligature of the second and third parts of the subclavian (fig. 1089).—Here the following three sets of vessels are those chiefly employed:—

The transverse scapular, the transverse cervical,	with	The thoracoacromial, infra- and supra-scapular, and circumflex scapular
The superior intercostal, the aortic intercostals, and the internal mammary,	with	The lateral thoracic and subscapular arteries
Numerous unnamed branches passing through the axilla from branches of the subclavian,	with	Branches of the axillary.

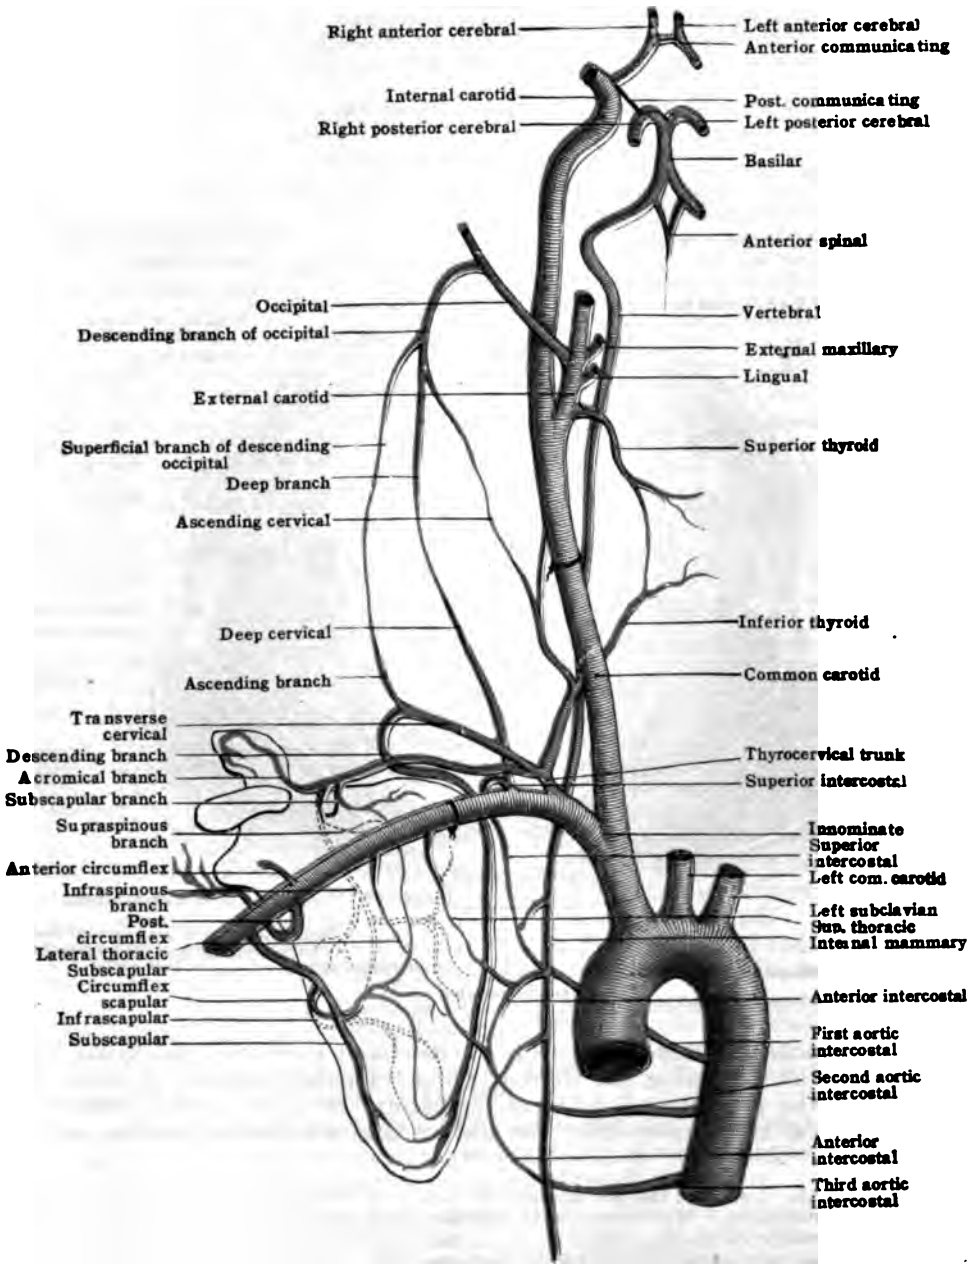
Deep cervical fascia.—The arrangement of this must be remembered—(*a*) above, and (*b*) below, the hyoid bone. The latter is far more important (fig. 381

(*a*) **Arrangement above the hyoid bone.**—Here two chief processes can be made out:—one, continuous with that in front of the sternomastoid, traced upward from the hyoid bone

encloses the submaxillary gland, passing over the mylohyoid, and, ascending, is connected with the lower border of the mandible, gives off the masseteric and parotid fasciæ, and is attached to the lower border of the zygoma, and, more posteriorly, to the mastoid and linea nuchæ suprema. (ii) A special process, which forms the stylomandibular ligament, is important in its power of checking overaction of the external pterygoid. By both these processes the ante-

FIG. 1089.—THE COLLATERAL CIRCULATION AFTER LIGATURE OF THE COMMON CAROTID AND SUBCLAVIAN ARTERIES.

(A ligature is placed on the common carotid and on the third portion of the subclavian artery.)



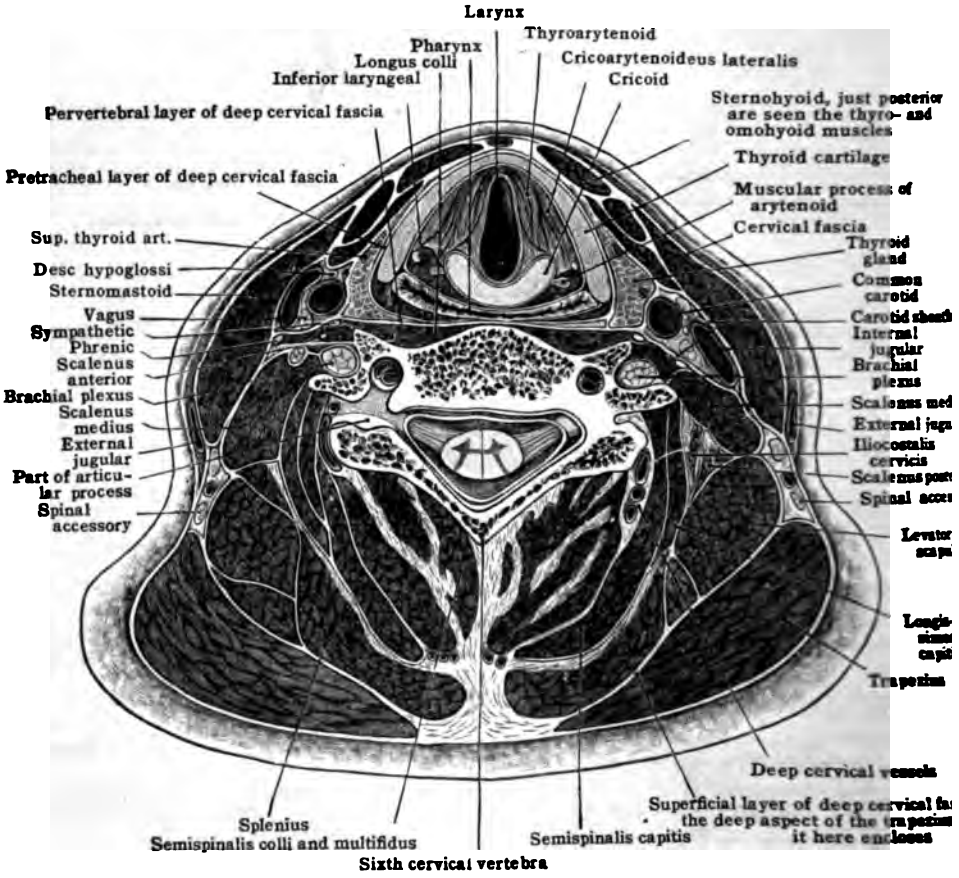
rior border of the sternomastoid is tied firmly forward to the mandible about its angle, and more deeply to the styloid process. This renders all operations under the upper part of the muscle, e. g., the removal of glands, extremely difficult.

(*b*) **Below the hyoid bone** (figs. 381, 1090).—The importance of the fascia here is much greater. **Four layers** must be remembered: (1) **Superficial**; (2) **pretracheal**; (3) **prevertebral**; (4) **carotid.** (1) **Superficial:** This starts from

the ligamentum nuchæ, encases the trapezius, forms the roof of the poster triangle where it is perforated by branches of the superficial cervical nerves a the external jugular vein. Passing on it encloses the sternomastoid and, pass over the anterior triangle, it meets its fellow in the middle line.

Thin behind, it is thickened anteriorly. Behind this thickened union lie the ant jugular veins. Below, at a varying distance below the thyroid cartilage, this layer div into two, attached to the front and back of the manubrium. Between these (Burn's spa lie some fat, a small gland, a communicating branch between the anterior jugulars and a se portion of the veins, and the sternal heads of the sternomastoids. The sheath to the depres of the hyoid bone is partly derived from this layer, partly from the next. Laterally, this la gives a sheath to the posterior belly of the omohyoid, is attached to the clavicle, and pass on, is continuous with the sheath to the subclavius and coracoclavicular fascia.

FIG. 1090.—SECTION OF NECK THROUGH THE SIXTH CERVICAL VERTEBRA. (Braune



(2) **Pretracheal or middle.** This lies under the depressors of the hyoid, e the trachea, also encasing the thyroid gland. Farther laterally it helps, gether with the prevertebral, to form the carotid sheath. Traced downw the pretracheal layer passes over the trachea into the thorax (middle me tinum).

As it descends, it encases the left innominate vein, and ends by blending with the fi layer of the pericardium. Hilton suggested that the attachment of this fascia above, and of the central tendon of the diaphragm below, to the pericardium served to keep this sac stretched, and so prevented any pressure of the lungs upon the heart.

(3) **Prevertebral.** This layer passes over the longus colli and capitis up to the base of the skull, and downward over the longus colli behind the esoph into the posterior mediastinum. Laterally it helps to form the carotid sh and, lower down, gives a sheath to the subclavian artery and so to the axil

(4) **The carotid sheath.** This is formed by septa from i, ii, and iii, meeting u the sternomastoid (fig. 1090).

The following **uses** and **important points** with regard to the anatomy of the deep cervical fascia should be noted:—(A) It **forms certain definitely enclosed spaces** in which pus or growths may form, and by the walls of which these morbid structures may be tied down and thus rendered difficult of diagnosis, while their increasing pressure may embarrass the air-passages, etc. Thus: (1) In the first space, which lies between the first layer and the skin, the structures met with, the platysma and superficial branches of the cervical plexus, are unimportant. Any abscess here is prone to extend, but superficially. (2) In the second space, between the superficial and middle layers, lies a narrow space containing loose cellular tissue and lymphatic glands. Suppuration here is very common, but usually comes forward. (3) This is the largest and most important of all. From its contents it has been called the **visceral compartment.** (Stiles.) It is bounded in front by the middle, and behind by the prevertebral layer. Its contents are—larynx, trachea, esophagus, thyroid, carotid sheath, glands; and below, brachial plexus, subclavian artery, and abundant loose cellular tissue for the movements of the neck. Suppuration is somewhat rarer here; but either pus or growth, if confined in this space, may have baneful effects, from pressure, or from their tendency to travel behind the sternum. (4) This space between the prevertebral layer in front and muscles behind, is very limited. Retropharyngeal abscess forms here, and the dyspnea it causes is thus explained. The origin of such abscesses is chiefly twofold, either in one of the highest deep cervical nodes, e. g., from infection of the nasopharynx (p. 751), or from disease of the upper cervical vertebræ. In the former cases (Stiles, Chiene) the suppuration will be *in front* of the prevertebral fascia, pointing toward the pharynx; in the latter *behind* the above fascia, spreading laterally, behind the carotid sheath. In making his incision, now along the posterior border of the sternomastoid, the surgeon should keep close to the transverse processes of the vertebræ, to avoid opening the visceral compartment and infecting the structures in it. (B) The deep cervical fascia gives **sheaths** or **canals** to certain veins which perforate it, e. g., the external jugular. These are thus kept patent, and a ready passage of blood ensured from the head and neck. Further, this fact accounts for the readiness with which air may enter veins, in operations low down in the neck. The carotid sheath is another and different instance. (C) It **helps to resist atmospheric pressure.** (D) Hilton's suggestion as to **its action on the pericardium** has already been mentioned.

The lymphatic nodes of the head and neck have already been described. (See Section VII, LYMPHATIC SYSTEM.)

THE THORAX

The bony landmarks of the thorax will be discussed first, followed by the structures of the thoracic wall, the lungs and pleura, and finally the heart and pericardium.

Bony landmarks.—The top of the sternum (figs. 203, 983, 1084) usually corresponds to the disk between the second and third thoracic vertebræ, and is distant about 6.2 cm. (2½ in.) from the vertebral column. In the newborn child it corresponds to the middle of the first thoracic vertebra (Symington). If traced downward, the subcutaneous sternum presents a ridge (sternal angle of Louis) at the junction of the manubrium and body, and the second costal cartilages on either side: this ridge usually corresponds to the disk between the fourth and fifth thoracic vertebræ. At the lower extremity of the sternum the xiphoid cartilage usually retires from the surface, presenting the depression of the epigastric angle or 'pit of the stomach.' This is opposite to the seventh costal cartilages and corresponds to the tenth thoracic vertebra behind.

Parts behind manubrium.—There is little or no lung behind the manubrium, the space being occupied by the trachea and large vessels, as follows:

The left innominate vein crosses behind the sternum just below its upper border. Next come the great primary branches of the aortic arch. Deeper still is the trachea, dividing into its two bronchi opposite to the sternal angle. Deepest of all is the esophagus. About 2.5 cm. (1 in.) below the upper border of the sternum is the highest part of the aortic arch, lying on the bifurcation of the trachea. (Holden). (Fig. 1091).

Sternoclavicular joint (fig. 315).—The expanded end of the clavicle and the lack of proportion between this and the sternal facet, on which largely depends the mobility of the joint, can easily be made out through the skin.

The strength of the joint, considerable when the rarity of dislocation compared with fracture of the clavicle is considered, depends mainly on its ligaments, the buffer-bond meniscus, the costoclavicular ligament, which checks excessive upward and backward movements, and the fact that the elastic support of the first rib comes into play in strong depression of the shoulder as in carrying a weight. The relative weakness of the anterior ligament determines the greater frequency of anterior dislocation of the clavicle at this joint. Behind the joint lie, on the right side, the innominate artery, right innominate vein, and pleura; on the left, the left innominate vein, the left carotid, and the pleura.

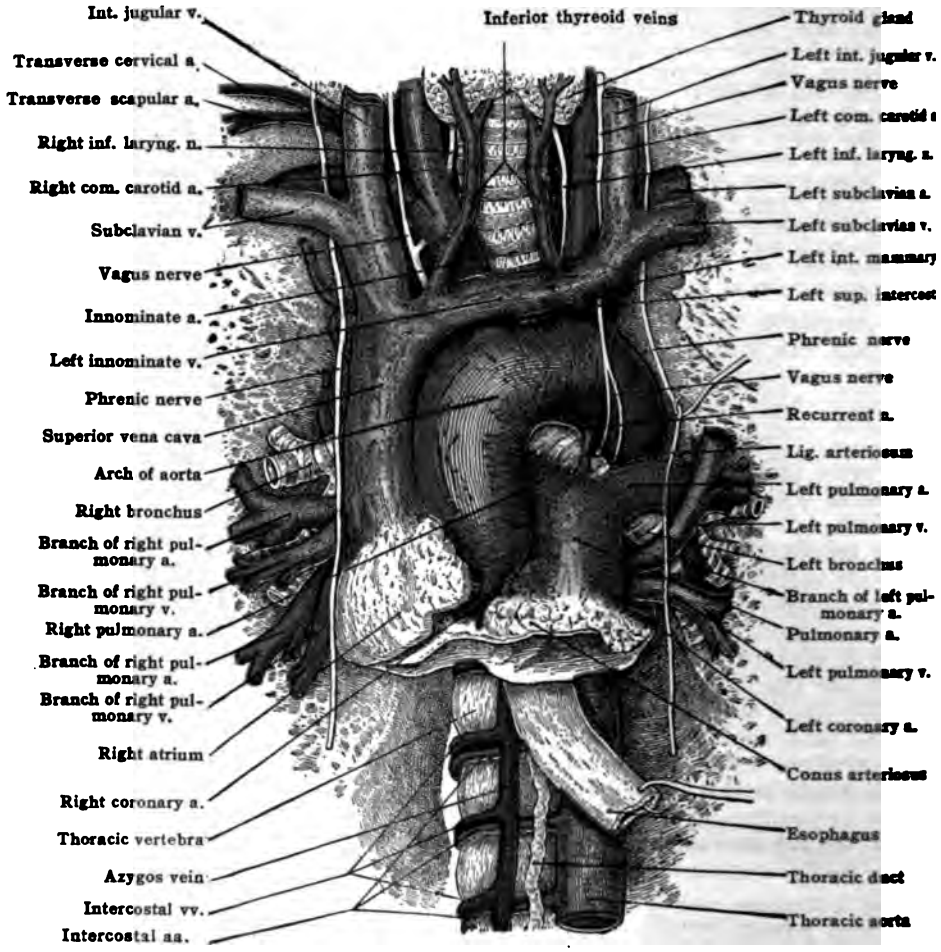
Acromioclavicular joint (figs. 319, 320).—On tracing the clavicle laterally, it is found to rise somewhat to its articulation with the acromion. This joint has

very little mobility, and owes its protection to the strong conoid and trapez ligaments near by. Owing to the way in which the joint-surfaces are bevell that of the clavicle looking obliquely downward, and resting upon the acromi upward displacement of the clavicle is more frequent.

Ribs.—In counting these, the position of the second is denoted by the tra verse ridge (sternal angle) at the junction of the manubrium and body of t sternum. It is well always to count ribs from this point and never from below. the twelfth rib varies in size and may be obscured by the sacrospinalis musc

FIG. 1091.—THE ARCH OF THE AORTA, WITH THE PULMONARY ARTERY AND CHIEF BRANC OF THE AORTA.

(Modified from a dissection in St. Bartholomew's Hospital Museum.)



The *nipple* in the male, lies between the fourth and fifth, nearly an inch late to their cartilages. The lower border of the great pectoral corresponds to t fifth rib. The seventh, the longest of the ribs, is the last to articulate by cartilage with the sternum. When the arm is raised, the first three digitatic seen of the serratus anterior correspond to the fifth, sixth, and seventh ribs. T ninth rib is the most oblique. The eleventh and twelfth can be felt lateral the sacrospinalis. Owing to the obliquity of the ribs, their sternal ends are o much lower level than their vertebral extremities.

'Thus the first rib in front corresponds to the fourth rib behind, the second to the si the third to the seventh, the fourth to the eighth, the fifth to the ninth, the sixth to the te and the seventh to the eleventh. If a horizontal line be drawn round the body from before ba ward at the level of the inferior angle of the scapula, while the arms are at the sides, the l would cut the sternum in front between the fourth and fifth ribs, the fifth rib at the nipple li and the ninth rib at the vertebral column.' (Treves.) The most frequently broken are

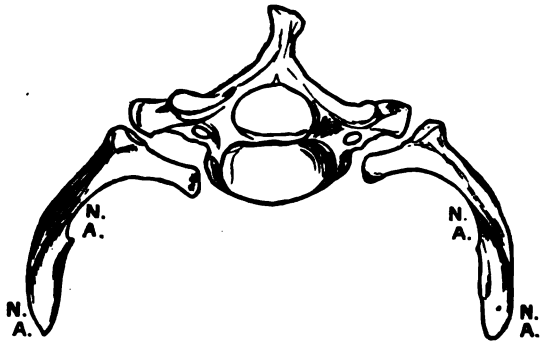
sixth, seventh, and eighth. The upper four and the two lowest ribs are best covered by soft parts, and, in the case of the former, the shoulder and arm take off some of the violence that would otherwise reach them. The way in which the ribs are embedded in the soft parts (fig. 1093), and the fact that the fragments are often held in place by the periosteum, account for the difficulty which is often met with in detecting crepitus. The intercostal spaces are wider in front than behind. The three upper are the widest of all.

Cervical ribs.—It occasionally happens that the rib-element of the seventh cervical vertebra, normally fused with the true transverse process, is segmented off as a separate, though usually rudimentary, rib. This anomaly is generally bilateral (fig. 1092). It occurred in 3 of 260 subjects (1.16 per cent.) examined by Wingate Todd (Jour. Anat. and Physiol., vol. 47, 1913). (See also p. 177.)

The anterior extremity of a cervical rib may, according to the degree of its development (1) lie free among the scalene muscles; (2) be connected with the sternum by a ligamentous prolongation; (3) articulate with the upper surface of the first thoracic at about its center by a synchondrosis, or (4) form a complete rib, articulating by a costal cartilage with the sternum.

The lowest trunk of the brachial plexus formed by the eighth cervical and first thoracic roots, the subclavian artery and less commonly the subclavian vein, curve over the upper surface of these ribs or over a ligament stretched from the first rib to the tip of the cervical rib. The abnormality owes its clinical importance to the pressure effects produced on the nerves

FIG. 1092.—CERVICAL RIBS, VIEWED FROM ABOVE. (× ½.) NN, IMPRESSION FOR LOWEST TRUNK OF BRACHIAL PLEXUS. AA, IMPRESSION FOR SUBCLAVIAN ARTERY. (T. WINGATE TODD.)



(especially the ulnar) in a small proportion of the cases. This pressure is manifested by (1) pain, going on to anesthesia down the medial side of arm, forearm and hand; (2) paralysis of the intrinsic muscles of the hand, producing the *main en griffe*, and to a less extent of the muscles of the forearm; (3) vascular effects (anemia, gangrene, etc.), manifested chiefly in the hand. Todd has shown that these vascular effects are not due to mechanical pressure on the subclavian artery by the cervical rib as was formerly supposed, but are trophic lesions of the sympathetic (vasomotor) nerves. The vasomotor nerves to the arm mainly come from the second thoracic root by the communication it gives to the lowest cord of the brachial plexus, and so are exposed to pressure from the rib.

The symptoms associated with cervical ribs usually develop about the 18th. year. Todd has shown that similar symptoms may be produced occasionally by a first thoracic rib in cases where the brachial plexus has migrated caudad. In the living patient, unless a radiogram be taken showing all the vertebræ up to the base of the skull, it is not possible with precision to ascertain with which vertebra the highest rib present articulates.

Structures found in an intercostal space.—(1) Skin; (2) superficial fascia, with cutaneous vessels and nerves; (3) deep fascia; (4) external intercostal; (5) cellular interval between intercostals, containing trunks of intercostal vessels and nerves; (6) internal intercostals; (7) thin layer of fascia; (8) subpleural connective tissue; (9) pleura (fig. 1093).

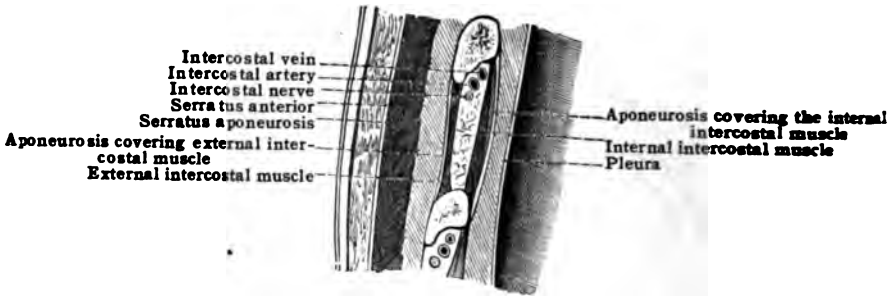
The *intercostal arteries* are nine aortic and two from the superior intercostal. An aortic intercostal having given off its dorsal branch, lying beneath the pleura, crosses the space obliquely upward to gain the lower border of the rib above, enters the costal groove at the angle, and runs forward between the intercostal muscles to anastomose with the anterior intercostals from the internal mammary or musculophrenic. Hence the rule of making the incision in empyema above the upper margin of the lower rib and in front of the angle. Along the dorsal branch a vertebral abscess may track backward.

Internal mammary artery (fig. 506).—This descends behind the clavicle, the costal cartilages, and the first six spaces, about 1.2 cm. (½ in.) from the edge of the sternum. In the sixth intercostal space it divides into musculophrenic and

superior epigastric arteries. Its venæ comitantes uniting join the innomi vein of the same side. A punctured wound of the artery is most easily secur the second and third spaces: below, resection of part of a costal cartilage wi needed.

Structures passing through the upper aperture of the thorax (388A, 98 If a section is made passing through the manubrium sterni, upper border o first rib, and upper part of the first thoracic vertebra, the following struct are met:—(1) **In the middle line.** Sternohyoid and sternothyroid muscles. their sheaths of deep cervical fascia, cellular tissue in which are the remains o thymus gland, the inferior thyroid veins, the trachea and tracheal fascia. esophagus, and longus colli muscles. Between the trachea and esophagus the recurrent nerves. (2) **On each side.** The apex of the lung, covered pleura, deep cervical fascia, and membranous cervical diaphragm ('Sibs fascia') derived from the scalenes, rises about 3.7 cm. (1½ in.) above the first Between it and the trachea and esophagus lie the following: the internal m mary artery, the phrenic nerve: on the right side, the innominate vein and art with the vagus between the two, the cardiac nerves, and the right lymph duct. On the left side are the common carotid and subclavian arteries, with left vagus between them, the cardiac nerves and the thoracic duct. Furth back and on each side are the trunk of the sympathetic, the superior interco artery, and the first thoracic nerve.

FIG. 1093.—SECTION OF THE SIXTH LEFT INTERCOSTAL SPACE, AT THE JUNCTION OF T ANTERIOR AND POSTERIOR THIRDS. (Tillaux.)



The mamma (figs. 80–83).—This lies chiefly on the pectoralis major s slightly on the rectus abdominis and serratus anterior. It is usually describ as reaching from the second to the sixth rib, and from the sternum to the anter border of the axilla. It is most important to remember that the breast is ofte much more extensive structure than would be included in the above very limit description. Thus—(1) the gland is not encapsuled at its periphery, its tis branching and breaking up here to become continuous with the superficial fas (Stiles.) (2) The retinacula cutis contain lymphatics and, sometimes, mamm tissue. (3) There is a lymphatic plexus, and, often, minute lobules of gl tissue, in the pectoral fascia. (Heidenhain.) Fully one-third of the wh mamma lies posterior and lateral to the axillary border of the pectoralis major that it reaches almost to the midaxillary line. That part of the upper and late quadrant known as the axillary lobe is of especial importance from its rea ing into close vicinity with the anterior pectoral group of axillary nodes (p. 7 In the male the nipple is usually placed in the fourth space, nearly 2.5 cm. (1 i lateral to the cartilages of the fourth and fifth ribs. On the nipple itself open fifteen or twenty ducts which dilate beneath it, and then diverge and break for the supply of the lobules. The skin over the areola is very adherent, p mented, and fatless. Here also are groups of little swellings corresponding large sebaceous follicles and areolar glands. The skin over the breast is fre movable, and united to the fascia which encases the organ, and thus to the int lobular connective tissue, by bands of the same structure—the retinacula cu Under the breast, and giving it its mobility, is a fatty areolar layer, the seat submammary abscess.

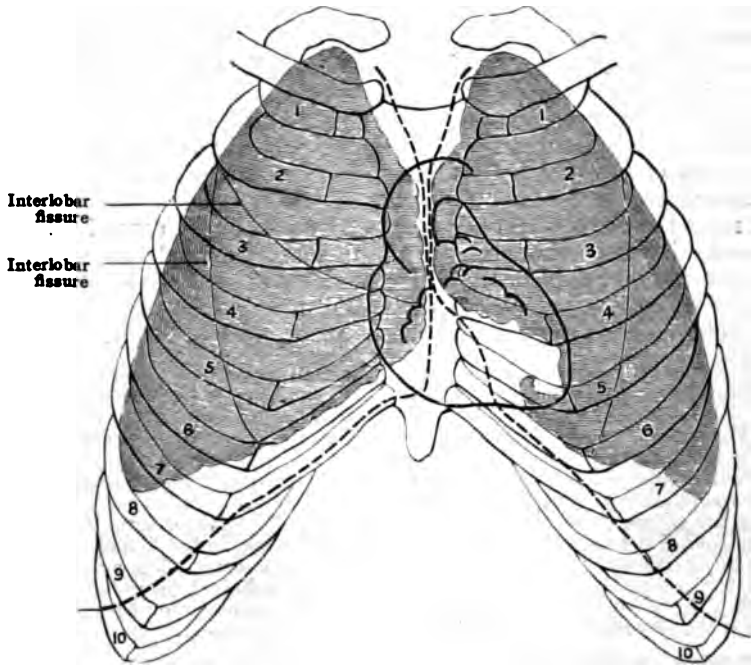
The nerves which supply the breast are the anterior cutaneous branches of the sec third, fourth, and fifth intercostal nerves, and the lateral branches of the last three. connection of these trunks serves to explain the diffusion of the pain often observed in pai

affections of the breast. Thus pain may be referred to the side of the chest and back (along the above intercostal trunks), over the scapula, along the medial side of the arm (along the intercostobrachial nerve), or up into the neck. The gland is supplied by the following **arteries**: the aortic intercostals of the second, third, fourth, and fifth spaces, similar intercostal branches from the internal mammary, which runs outward, two small branches to each space, perforating branches from the same vessel, one or two given off opposite to each space, the long thoracic and external mammary (when present) from the axillary.

The **lymphatics of the breast** require special attention. They follow along the milk-ducts to form the subareolar lymphatic plexus, from which the main lymphatic channels pass outward to communicate with the pectoral, subscapular, axillary and central nodes of the axilla.

There are three subsidiary or secondary lymphatic channels of the brest: (1) Groszman's path passes directly backward through the pectoralis major to communicate with lymph nodes (Rotter's) beneath the pectoralis minor. (2) Lymphatics which follow the perforating branches of the internal mammary to communicate with the mediastinal nodes and pleural lymphatics. (3) The paramammary route of Gerota, which may account for liver metastases and skin metastases in the upper abdominal wall. The lymphatics of the skin also anastomose across the front of the chest. For further details and figures, see pp. 756.

FIG. 1094.—OUTLINE OF THE HEART, ITS VALVES, THE LUNGS (SHADED), AND THE PLEURA. (Holden.) (Cf. figs. 481 and 1013.)



In **removal of the breast** elliptical incision will usually suffice if employed on wide lines and if attention be paid to the following points:—(1) Those details in the surgical anatomy already referred to, especially those bearing on the extensiveness of this organ, and the proportionate difference between seen and unseen disease. (2) The importance of removing in one continuous piece the whole breast, all the skin over it, the costosternal part of the pectoralis major, the pectoralis minor, the axillary fat, and lymphatics.

Surface form and relations of the lungs.—To map out the lung, a line should be drawn from the apex, a point about 2.5 cm. (1 in.) or less above the clavicle, a little lateral to the sternoclavicular articulation, obliquely downward, behind the sternoclavicular joint to near the center of the junction of the manubrium and body of the sternum (sternal angle). Thence, on each side a line should be drawn slightly convex as far as a similar point on the sternum lying opposite the articulation of the fourth chondrosternal joint. On the right side the line may be dropped as low as the sixth chondrosternal joint; on the left the incisura cardiaca may be shown by drawing a line lateralward to the parasternal line (midway between sternum and nipple) thence curving downward and medially to the sixth costal cartilage, a little lateral to its chondrosternal junction (fig. 1094). Thus the lower part of the anterior surface of the right ventricle is not covered by lung. The lower border of the lung will be marked on the right side by a line drawn from the sixth chondrosternal articulation across the side of the

chest down to the tenth thoracic spine. The lower border of the left lung wi follow a similar line, starting on a level with the sixth chondrosternal join In the nipple-line the lung crosses the sixth rib, in the midaxillary line the eigh and opposite the angle of the scapula (the arms being close to the sides), the ten rib. The position of the great fissure in each lung may be ascertained appro mately by drawing a line curving downward and forward from the second thora spine to the lower border of the lung at the sixth costal cartilage: and the small (horizontal) fissure of the right lung extends from the middle of the foregoing the junction of the fourth costal cartilage with the sternum. It will be seen fr the above that there is little lung behind the manubrium. The connective tis here between the lung margins contains the thymus, large up to the age of puber and, later, its remains. The hilus (root) of the lung is referred to on p. 12 For further details on the topography of the lungs, see p. 1265.

The border of the **pleura** (fig. 1094), following much the same line as the lu above and in front, reaches lower down laterally and behind. Thus the t sacs starting from about 2.5 cm. (1 in.) above the medial third of the clavi converge toward the sternal angle (p. 1260); meeting here, they descend ve cally, the left overlapping the right slightly, to the fourth chondrosternal joi Hence the *right* sac descends behind the sternum to the sternoxiphoid junct and sixth chondrosternal joint. Thence, as it curves backward on the chest, cr ing the eighth rib close to the parasternal line (*vide supra*), the tenth in the m axillary, the eleventh in the line of the angle of the scapula, and thence toward twelfth thoracic vertebra. On the *left* side the pleura parts company from right at the level of the fourth chondrosternal junction, deviating laterally s downward across the fourth and fifth interspaces: it then turns again sligh medially to meet the sixth costal cartilage. Thus, as in the case of the lung, to a less extent, there is a small area of the pericardium, and, under it, the ri ventricle uncovered by the pleura. Over the side and back of the chest, along diaphragmatic reflection, the left pleura reaches a little lower than the rig For further details on the topography of the pleura, see p. 1260).

The *deepest part of the pleural sac* is where the reflection crosses the tenth rib or tenth sp in the midaxillary line. From this it ascends slightly as it curves back to the spine. (C ningham.) *The relations of the pleura to the last rib* are of much importance to the surgeo operations on the kidney. In the case of a twelfth rib of ordinary length, the pleural reflect crosses it at the lateral border of the sacrospinalis; when a rudimentary last rib does not re the lateral border of this muscle, an incision carried upward into the angle between the eleve rib and the sacrospinalis will open the pleural sac. (Melsome.)

For **tapping the pleura** there are two chief sites:—(1) The sixth or seventh space in fr of the posterior fold of the axilla. (2) The eighth space behind, in the line of the angle of scapula. For **the incision of an empyema** the first is usually chosen. The overlying soft pa are not thick, the interspace is wide enough, drainage is sufficient (especially if part of seventh or eighth rib be resected), and this site is free from the objection that the angle of scapula overlaps the seventh and eighth ribs, unless the arm is raised.

Surface form and relations of the heart (figs. 481, 1097).—The upper limit the heart (base) is defined by a line crossing the sternum a little above the upp border of the third costal cartilage, reaching about 1.2 cm. ($\frac{1}{2}$ in.) to the rig and about 2.5 cm. (1 in.) to the left of the sternum. Its apex point is in t fifth space, 3.7 cm. ($1\frac{1}{2}$ in.) below the male left nipple, and 2.5 cm. (1 in.) to t medial side. This point will be about 7.5 cm. (3 in.) from the midline. T right border (right atrium) will be given by a line, slightly convex laterally, dra from the right extremity of the upper border to the right sixth chondroster joint. If another line, slightly convex upward, be drawn onward from this po across the last piece of the sternum, just above the xiphoid cartilage, to the ap it will give the lower border (margo acutus of right ventricle), which rests on t central tendon of the diaphragm. The left border (margo obtusus of left vent cle) will be given by a line, convex to the left, passing from the left extremity the upper border to the apex-point. This line should be 7.5 cm. (3 in.) from t middle of the sternum at the level of the fourth costal cartilage. The base of t heart is opposite four of the thoracic vertebræ, viz., the sixth, seventh, eight and ninth. The apex and anterior or sternocostal surface have been mentione The inferior or diaphragmatic surface (chiefly left atrium and left ventricle) re upon the diaphragm, mainly the central tendon, to which the intervening pe cardium is connected, and is thus adjacent to the liver and a small portion of t stomach.

If a circle 5 cm. (2 in.) in diameter be described around a point midway between the left nipple and the lower end of the body of the sternum, it will define with sufficient accuracy for practical purposes that part of the heart which lies immediately behind the chest wall, and which is uncovered by lung and (in part) by pleura. (Latham.)

The valves.—The **pulmonary valves** (the highest and most superficial) lie, in front of the aortic, behind the third left chondrosternal joint, and opposite to the upper border of the third costal cartilage. The **aortic valves** lie behind and a little below these, opposite to the medial end of the third intercostal space, and on a level with the lower border of the third left costal cartilage. The **atrioventricular openings** lie at a somewhat lower level than that of the aortic and pulmonary. Thus the **tricuspid valves** lie behind the middle of the sternum at the level of the fourth intercostal space; and the **mitral valves,** the most deeply placed of all, lie a little to the left of these, behind the left edge of the sternum and the fourth left costal cartilage (fig. 1094: also cf. fig. 481).

'Thus these valves are so situated that the mouth of an ordinary-sized stethoscope will cover a portion of them all, if placed over the juncture of the third intercostal space, on the left side, with the sternum. All are covered by a thin layer of lung; therefore we hear their action better when the breathing is for a moment suspended.' (Holden.)

The pericardium.—This fibroserous sac, occupying the middle mediastinum, is triangular in outline. Here its fibrous layer gives investment to the large vessels, except the inferior cava. It is also continuous with the deep cervical fascia. The base, connected with the diaphragm, has been referred to above. In front an area of variable size (fig. 1094), owing to the divergence of the left pleura, is in contact with the left half of the lower part of the sternum, and more or less of the medial ends of the fourth, fifth, and sixth costal cartilages, here forming the posterior boundary of the anterior mediastinum. Behind, the pericardium is the anterior boundary of the posterior mediastinum, and is in close contact with the esophagus and aorta.

Paracentesis of pericardium.—While the seat of election must here remain an open question, each case requiring a decision for itself, the one most suitable on the whole is the fifth left space, avoiding injury to the internal mammary artery and the pleura, of which the line of reflection has been shown to vary.

In **incision of the pericardium** to establish free drainage, a portion of the fifth or sixth left costal cartilage should be carefully resected, the internal mammary artery tied, the transversus thoracis (triangularis sterni) scratched through, and the pleural reflection pushed aside.

Relation of vessels to the wall of the thorax.—**Aortic arch.**—The ascending part of the aorta reaches from a spot behind the sternal border, on a level with the third left costal cartilage, to the upper border of the second right cartilage; thus it passes upward, backward, and to the right, and is about 5 cm. (2 in.) long. The transverse part then crosses backward to the left behind the sternum (the highest part of the arch being about 2.5 cm. below the notch), reaching from the second right costal cartilage to the lower border of the fourth thoracic vertebra on the left side. This part recedes from the surface, and, with the next, cannot be marked out on the surface. The third, or descending part, the shortest of the three, reaches from the lower border of the fourth to that of the fifth thoracic vertebra.

FIG. 1094 will remind the reader of many of the pressure symptoms which may accompany an **aneurysm of the aortic arch;** e.g., pressure on the left innominate vein, the three large arteries, trachea, and left bronchus, recurrent nerve, esophagus, and thoracic duct. In **aneurysm of the thoracic aorta,** pain, usually unilateral, referred to the corresponding intercostal nerves, is a common pressure symptom.

The pulmonary artery lies behind the left side of the sternum and its junction with the second and third costal cartilages.

Innominate artery.—A line drawn from the top of the arch, about 2.5 cm. (1 in.) below the sternal notch, and close to the center, to the right sternoclavicular joint, will give the line of this vessel.

Left common carotid.—This vessel will be denoted by a line somewhat similar to the above, passing from the level of the arch a little to the left of the last starting-point to the left sternoclavicular joint.

Left subclavian artery.—A line from the end of the transverse arch, behind the left of the sternum, straight upward to the clavicle, delineates the vertical thoracic course of the long left subclavian artery; its thoracic portion lies behind the left carotid.

Innominate veins.—The **left,** 7.5 cm. (3 in.) long, extends very obliquely from the left sternoclavicular joint, behind the upper part of the manubrium, to a point 1.2 cm. (½ in.) to the right of the sternum, on the lower border of the first right costal cartilage. The **right,** about 2.5 cm. (1 in.) long, descends almost vertically to the above point from the right sternoclavicular joint.

Venæ cavæ.—The **superior** descends from the point above given for the meeting of the innominate veins in the first intercostal space, close to the sternum, and perforates the right atrium on a level with the third costal cartilage. The **inferior vena cava.**—The opening of this vein into the right atrium lies under the middle of the fifth right interspace and the adjacent part of the sternum.

The esophagus.—The relations of this tube (figs. 913, 914) in its cervical a thoracic portions are most important, e.g., to the trachea and left bronchus: t vagi and left recurrent nerve; the pleuræ, left above and right below, aorta, a pericardium. Its lymphatics (fig. 612) go below into the posterior mediasti and superior gastric nodes; above into the lower deep cervical nodes, a p sometimes diagnostic in malignant disease.

The lumen of the esophagus is narrowed at three points:—(1) and best marked at the coid cartilage, (2) where it is crossed by the left bronchus, (3) as it passes through the phragm. The tube, 25 to 27 cm. (10 to 11 in.) long, extends from the sixth cervical to the lo border of the tenth thoracic vertebra. In an adult, the distance from the incisor teeth to cricoid is about 15 cm. (6 in.); an additional 7.5 cm. (3 in.) gives the level of the crossin the left bronchus, while from the teeth to the opening in the diaphragm would be from 41 to cm. (16 to 17 in.). The upper part of the esophagus just below the cricoid cartilage poster has a weak spot. The mucous membrane may herniate at this point giving rise to esopha diverticula. To expose the tube in the neck an incision is made on the left side, much as for higher ligature of the common carotid, but carried lower down. The depressors of the h being drawn medially or divided, the pretracheal fascia is opened, which allows of the over ping thyroid and trachea being displaced medially, while the carotid sheath is retracted la ally. The tracheal rings are the best guide to the esophagus. The recurrent nerve mus avoided.

THE ABDOMEN

The regions and subdivisions will first be considered, the abdominal w next, and finally the abdominal cavity, including the peritoneum and the vari organs.

Subdivision of the abdominal cavity.—Certain arbitrary horizontal vertical planes, represented by lines drawn on the ventral surface, are used subdivide the abdomen for topographical purposes (fig. 916). **A. Horizo planes:** (1) *Infracostal* through the lower margins of the tenth costal cartila (the lowest part of the costal margin). This plane crosses the body of the th lumbar vertebra. (2) *Intertubercular*, passing through the tubercles, promin points of the iliac crests, which are situated about 5 cm. (2 in.) behind the ante superior spines. This plane crosses the body of the fifth lumbar vertebra. **Vertical planes:** (1) *Median vertical*, drawn upward in the middle line from symphysis pubis. (2) *Lateral vertical*, drawn upward on each side parallel to former, from a point midway between the anterior superior iliac spine and symphysis pubis.

These lateral lines if prolonged upward into the thorax pass rather more than 2.5 cm. (1 to the medial side of the male nipple and meet the clavicle a little medial to its midpoint.

According to the BNA system, the lateral vertical lines are slightly curved, extending ward from the pubic tubercle on each side along the lateral margin of the rectus muscle (co sponding to the linea semilunaris); and the lower horizontal is drawn between the ante superior iliac spines.

The infracostal and intertubercular planes, with the two lateral verti planes that intersect them divide the abdomen into nine regions;—three medi viz., the epigastric, umbilical, and hypogastric and on each side three lateral, v hypochondriac, lumbar, and iliac (fig. 916).

Another transverse plane of practical importance, though we do not use it as a bound of the abdominal subdivisions, is represented by Addison's transpyloric line (fig. 1095), dr horizontally through a point midway between the umbilicus and the sternoxiphoid junction midway between the symphysis pubis and suprasternal notch). It crosses the spine at the l the first lumbar vertebra. It must be noted that the pylrous only lies in this plane du life when the subject is in the horizontal position. On assuming the upright position the pyl falls at least one vertebra lower. The sternoxiphoid plane, drawn horizontally through junction of the body of the sternum with the xiphoid, cuts the spine at the disk between ninth and tenth thoracic vertebræ, and the umbilical plane, passing through the umbili crosses the disk between the third and fourth lumbar vertebræ (though in corpulent subjects i somewhat lower).

The abdominal wall. Bony and muscular landmarks.—The linea a (see p. 460) forms a perceptible groove in the middle line from the xiphoid c tilage to the umbilicus. It is a band of interlacing fibers, mostly crossing ea other at right angles, that forms the main insertion of the transversus and obliq muscles, and stretches between the two recti muscles from xiphoid cartilage symphysis. It is on the average 1.2 cm. ($1\frac{1}{2}$ in.) wide above the umbilic Below the umbilicus it narrows rapidly and becomes merely a thin fibrous septu between the two recti, which in this position lie close together.

In its broad supraumbilical portion, small hernial protrusions of subperitoneal fat sometimes force their way through interstices in the linea alba, and true peritoneal sacs may be drawn through after them. Subperitoneal fat usually forms the greater part of such a protrusion. The linea alba is not very vascular, and hence was at one time the favorite site of incisions in opening the abdominal cavity. Since the resulting scar is weak and yielding, however, it is now more customary to make vertical incisions through the rectus sheath, to one side of the middle line, where the abdominal wall can be sutured in layers, and an incisional hernia prevented.

The umbilicus lies in the linea alba rather below its center. It is somewhat prone to hernia formation (p. 1402) and is occasionally the site of congenital fistulæ, which may originate in a Meckel's diverticulum (p. 1376) or a patent urachus.

When the recti are thrown into contraction the **linea semilunaris** on each side is made evident as a groove, extending with a slight lateral convexity from the tip of the ninth costal cartilage, where the lateral vertical line meets the thoracic margin, to the pubic tubercle.

The linea semilunaris shares the disadvantages of the linea alba as a site for incisions, and there is the further danger of injury to the nerve supply of the rectus, which may involve a diffuse bulge of the atrophied muscle.

The contraction of the recti muscles also shows up the three *lineæ transversæ*, fibrous intersections adherent to the anterior layer of the sheath of the rectus, which cross the substance of the muscle (1) at the umbilicus, (2) at the tip of the xiphoid, and (3) midway between the former two. A tonic contraction of one or both recti localised to one of these segments occasionally gives rise to the 'phantom' tumors which occur in some hysterical cases.

In tapping the bladder above the pubes, the trocar should be introduced immediately above the pubes and driven backward and a little downward. In this operation, and in suprapubic cystotomy, the retropubic (prevesical) space or **cavum Retzii** is opened (cf. figs. 1025, 1046). This is bounded anteroinferiorly by the pubes and superior fascia of the urogenital diaphragm, posterosuperiorly by the anterior surface of the bladder. Below are the true ligaments of this viscus. The space contains fatty tissue and veins, increasing in size with the advance of life. If about ten ounces of fluid are injected nto the bladder, the peritoneum will be raised sufficiently to allow of a three-inch incision being made between the recti and pyramidales immediately above the pubes. The transversalis fascia is thicker below, and is often separated from the linea alba by fat, which must not be mistaken for the extraperitoneal layer. The peritoneal reflection is loosely connected to the bladder and can always be peeled upward.

A transverse line drawn from one anterior superior iliac spine to the other crosses at about the level of the top of the promontory of the sacrum. Such a line will always show whether the pelvis is horizontal or not. (Holden.)

The **inguinal (Poupart's) ligament** (fig. 1109) corresponds to a line drawn with a slight curve downward between the anterior superior iliac spine and the pubic tubercle. The first of these bony prominences corresponds to the starting-point of the above ligament, the attachment of the fascia lata to the ilium, the meeting of the fleshy and aponeurotic parts of the external oblique (denoted by a line drawn upward from this spine to the ninth costal cartilage, or often a little anteriorly to these points), the point of emergence of the lateral cutaneous nerve of the thigh, and part of the origins of the internal oblique, transversus, and tensor fasciæ latæ.

The pubic tubercle marks the lateral pillar (inferior crus) of the **subcutaneous inguinal (external abdominal) ring**, the mouth of which corresponds to the crest of the pubes lying between the tubercle and the symphysis. The neck of an inguinal hernia is above the tubercle and Poupart's ligament; that of a femoral hernia below and lateral to the tubercle, and below the same ligament. The ring, and especially its lateral pillar, can easily be felt by invaginating the scrotal skin with a finger, and pushing upward and laterally. In a female patient, if the thigh be abducted, the tense tendon of the adductor longus will lead up to the site of the ring. The **abdominal inguinal (internal abdominal) ring** is situated about 1.2 cm. (½ in.) above the center of Poupart's ligament; oval in shape, and nearly vertical in direction, it has the arching fibers of the transversus above it, and to its medial side the inferior epigastric artery, lying behind the spermatic cord. The pulsations of this vessel here guide the finger in the insertion of the uppermost deep sutures in radical cure of hernia. The **canal** runs obliquely downward and forward between the two rings. In the adult it is about 3.7 cm. (1½ in.) long, but in early life, and in adults with a large hernia dragging upon the parts, the two rings are much nearer, and may be one behind the other. For the anatomy of this region and of inguinal hernia, see pp. 463 and 1394.

Vessels in the abdominal wall (fig. 535).—The three superficial branches of the common femoral, the external pudic, epigastric, and circumflex iliac, supply the lowest part of the anterior abdominal wall and the adjacent groin and genitals.

The others that have to be remembered are the inferior epigastrics and epigastric branch of the internal mammary, the deep circumflex iliacs, the two intercostals, and the abdominal branches of the lumbar arteries.

Of these, the inferior epigastric is the most important; its course will be marked out line drawn from a point just medial to the center of the inguinal ligament, upward and med to the medial side of the abdominal ring, and thence to a point about midway between the p and umbilicus, forming the lateral boundary of Hesselbach's triangle (fig. 1108). Here vessel, which at first lies between the peritoneum and fascia transversalis, perforates the l and, passing over the semicircular line (fold of Douglas) enters the sheath of the rectus. It runs upward, closely applied to the back of that muscle, and, a little above the level o umbilicus, divides into branches which anastomose with the epigastric branch of the int mammary.

One superficial vein in the abdominal wall needs especial mention, the thoracoepig (fig. 563) joining the veins of the chest, e. g., the long thoracic above with, the superficia gastric below. Its valves directing the blood downward below and upward above (Stiles) be rendered incompetent when this vessel is enlarged, as in interference with the portal with which it communicates by a vein in the round ligament, or in blocking of the inferior cava.

Lymphatics.—It is sufficiently correct to say that those above the umbilical level go t axillary, and those below that line to the inguinal nodes.

Nerves (figs. 794, 807).—The lower seven intercostals and the iliohypoga and ilioinguinal supply the abdominal wall. The sixth and seventh interco supply the skin over the upper epigastrium; the eighth, the area of the mi linea transversa; the tenth, that of the umbilicus; the last thoracic, ilioingu and iliohypogastric, the region above Poupart's ligament, and that of the pu The iliohypogastric supplies the skin over the subcutaneous inguinal (exte abdominal) ring; the ilioinguinal that over the cord and scrotum. The thoracic and iliohypogastric cross the iliac crest to supply the skin of the butt

The diaphragm.—The upper limit of the diaphragm (see. p. 469) rises t following levels in full expiration; Its central tendon to about the lower end o body of the sternum, or the seventh chondrosternal joint; the right half t fifth rib, or about 1 cm. (½ in.) below the nipple; the left half not rising quit high, i.e., to the fifth space, or 2.5 cm. (1 in.) below the nipple.

Topographical relations of abdominal viscera (fig. 1095).—These will inc the peritoneum, liver and bile passages, stomach, spleen, pancreas, intesti kidneys and ureters, and large abdominal vessels.

The peritoneal spaces.—The peritoneum presents certain potential spa determined by its various reflections from the parietes and abdominal visc In these spaces collections of fluid such as abscesses or extravasations from hol viscera or blood vessels may collect and become shut off by adhesions or over in various directions into neighboring spaces. The transverse mesocolon great omentum together form a shelf transversely placed, which divides greater sac into two main divisions—supraomental and infraomental (figs. 9 923, 924).

The supraomental region, in which the various forms of subphrenic abscess are found. tains the following fossæ (Barnard, Brit. Med. Jour., Feb. 15, 1908). (1) Right subphr between the right lobe of the liver and right cupola of the diaphragm, bounded toward median line by the falciform ligament, and behind by the coronary ligament. It communic below with (2) the subhepatic fossa or right renal pouch (Morison), which is bounded abov the visceral surface of the liver, and below by the mesocolic shelf and right kidney. It ext from the right lateral abdominal wall, its most capacious part, across the median line under left lobe of the liver, and on its posterior aspect lie the upper pole of the right kidney, epi foramen, and anterior surface of small omentum. (3) The left subphrenic, also known as anterior perigastric fossa, lies between the left dome of the diaphragm above, and the left of the liver, stomach, spleen and omentum below. It is bounded on the right by the falci ligament which lies somewhat to the right of the median line. (4) The omental bursa ma regarded as a diverticulum from the subhepatic fossa with which it communicates by the ploic foramen. Abscesses in this sac are rare, but occasionally laceration of the panc or acute hemorrhagic pancreatitis gives rise to a collection of pancreatic juice and blood in lesser sac, known as a pancreatic pseudo-cyst (Jordan Lloyd).

The infraomental region is subdivided in its abdominal part into (1) right and (2) compartments by the attachment of the root of the mesentery to the spine, descending from duodenojejunal flexure downward into the right iliac fossa. These fossæ communicate with supraomental regions in the neighborhood of the hepatic and splenic flexures of the c respectively, and below with (3) the pelvis. The deepest level of the peritoneum lining pelvis constitutes in the male the rectovesical, and in the female the rectovaginal fossa (pouc Douglas). The mesentery extends obliquely from above to the left, downward and to the r from the 2nd to the 4th lumbar vertebra. Because of this oblique attachment, an abs

developing from a ruptured appendix which lies in the pelvis may be directed upward and to the left.

It should be noted that with a patient in the supine position, owing to the contour of the psoas muscles and the anterior convexity of the lumbar spine, any fluid above the pelvic brim will tend to gravitate into the subphrenic spaces across the flexures of the colon which lie far back in the loins. This is undesirable in view of the great absorbing power of the subphrenic lymphatics, and may be obviated by propping the patient in a half-sitting position.

Viscera behind the linea alba.—From above downward there are the following;—(1) *Above the umbilicus*—the left lobe of the liver, the stomach, the transverse colon, part of the great omentum, the pancreas; and celiac (solar) plexus. (2) *Below the umbilicus*—the rest of the great omentum, covering in the small intestines and their mesentery. In the child, the bladder occupies a partly abdominal position; and in the adult, the same viscus, if distended, will rise out of the pelvis and displace the above structures, raising the peritoneum until, if distended half way to the umbilicus, there is an area of nearly 5 cm. (2 in.) safe for operations above the symphysis. The gravid uterus also rises behind the linea alba.

The liver (figs. 917, 1095, 1113).—In the erect position, the anterior thin margin of the liver projects about 1 cm. (½ in.) below the right costal margin, but can only be made out with difficulty in this position. It may also be displaced downward by pleuritic effusion or tight lacing. The liver also is proportionately much larger in small children.

Of the three more accessible surfaces, *the right lateral* is opposite the seventh to the eleventh intercostal arches, separated from them by the pleura, the thin base of the lung, and the diaphragm. The *superior* surface is accurately fitted with its right and left portions into the hollows of the diaphragm, a slightly depressed area intervening which corresponds to the central tendon. Its level corresponds to that of the diaphragm given above. On the left side, in the adult, the limit of the left lobe will be in the fifth interspace, about 7.5 cm. (3 in.) from the midline. The *anterior* surface is in contact with the diaphragm, costal arches, and, between them, the xiphoid cartilage, and, below, with the abdominal wall. Both the superior and anterior surfaces are subdivided by the falciform ligament, an important point in subphrenic suppuration. In the right hypochondrium the anterior margin corresponds to the lower margin of the thorax; but in the epigastric region, running obliquely across from the ninth right to the eighth left costal cartilage, it crosses the midline about a hand's breadth below the sternoxiphoid articulation (Godlee), or half-way between the sternoxiphoid junction and umbilicus, i.e., in the transpyloric line (fig. 1095). Behind, the anterior margin, following the right lateral surface within the costal arches, crosses the last rib toward the level of the eleventh thoracic spine. In the anterior border, a little to the right of the midline, is the umbilical notch, where the falciform and round ligaments reach the liver. Still further to the right near the junction of the semilunar line and the infracostal margin, is the fundus of the gall-bladder.

Gall-bladder and bile-passages.—The fundus of the gall-bladder, situated in a fossa on the under surface of the right lobe of the liver, and having the quadrate lobe to its left, lies opposite to the right ninth costal cartilage, close to the lateral edge of the rectus. This point corresponds to the site of intersection of the lateral vertical and transpyloric lines (fig. 1095). It is near the hepatic flexure of the colon and the first part of the duodenum, into either of which, but particularly the latter, large gall-stones impacted in the neck of the gall-bladder occasionally ulcerate. A distended gall-bladder as it enlarges tends to extend downward or obliquely toward the umbilicus from the above point where it emerges from under the costal margin.

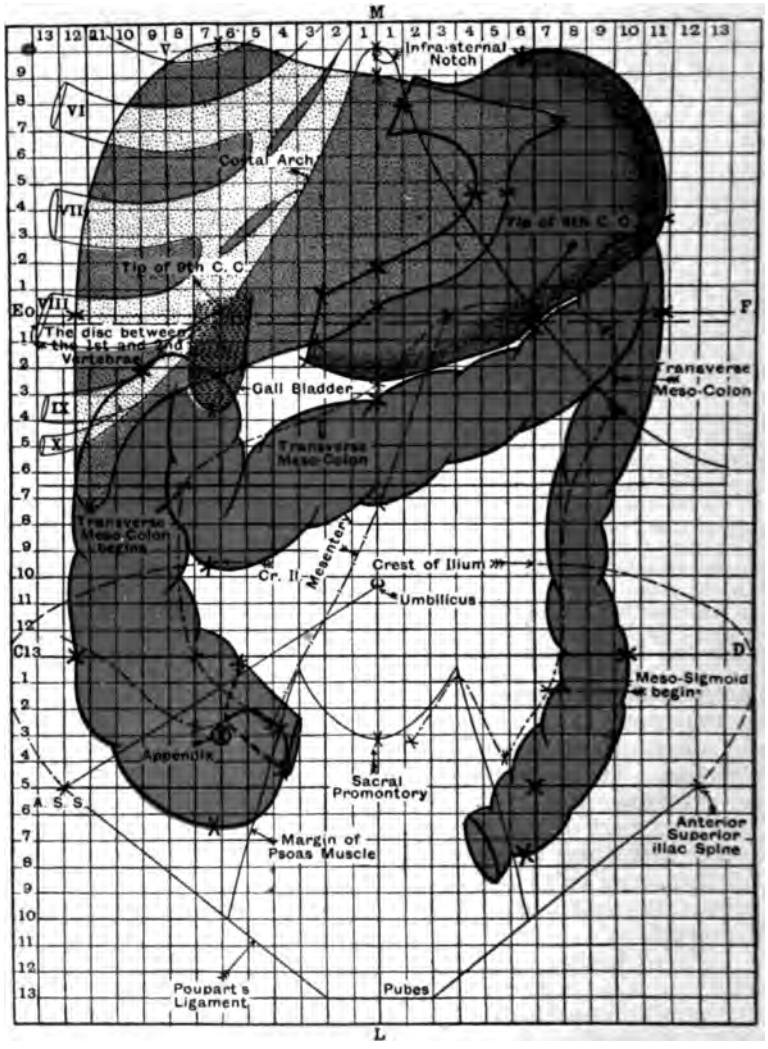
The long axis of the gall-bladder is directed from the fundus backward and upward. The cystic duct runs from the neck downward and forward in the lesser omentum, and so forms an acute angle with the gall-bladder. A spiral fold of mucous membrane at the junction of the two, which fulfils the function of keeping the lumen open for the flow of bile, adds to the difficulty of passing a bougie from the gall-bladder down into the common duct.

The hepatic and cystic ducts join in the right free margin of the lesser omentum to form the **common bile-duct**, 7.5 cm. (3 in.) in length, which as it runs down to open into the duodenum presents four distinct stages (figs. 933, 955, 962). (1) It first lies in the free edge of lesser omentum in front of the epiploic foramen, with the hepatic artery to the medial side, and the portal vein behind them both. (2) Behind the first part of the duodenum with the gastroduodenal artery accompanying it. (3) In a deep groove in the head of the pancreas, between that gland and the posterior aspect of the second part of the duodenum. The pancreatic tissue surrounds it completely in 75 per cent. of cases (Bunger), hence the jaundice that occurs in chronic interstitial pancreatitis. (4) Piercing the muscular wall of the duodenum obliquely it ends by joining the main duct of the pancreas at the ampulla of Vater and opening into the second part of the duodenum by a common orifice. This orifice, situated on the posteromedial aspect of the gut, rather below the center of the second portion, is raised on a small papilla and is narrower than the lumen of the common duct. It should be remembered that the cystic and right hepatic duct run parallel and rather close together for a short distance. Injury or

ligation of the hepatic duct occurs much too frequently in removal of the gall-bladder. d failure to realize the proximity of these two ducts.

The stomach.—The study of this organ by rendering its contents opaque bismuth salts and projecting its shadow by X-rays on a fluorescent screen greatly modified the conception of its shape and position formed from mortem and operative observations. Examined post-mortem, or at opera under general anesthesia it forms a flaccid sac with its long axis directed fro fundus obliquely downward, forward, and to the right (fig. 1095). Seen u

FIG. 1095.—OUTLINE SHOWING THE AVERAGE POSITION OF THE ABDOMINAL VISCE (Addison.)



X-rays, with the patient standing upright, the cardiac portion (the fundus body together) is vertical, and the smaller pyloric portion is directed back and to the right and slightly upward (figs. 926, 927, 1113). The most point is the cardiac orifice.

The **cardiac orifice** lies under the seventh left costal cartilage 2 cm. (¾ in.) from the s xiphoid junction at a depth of about 10 cm. (4 in.) from the surface. Behind, this point sponds to the tenth thoracic vertebra.

The **pyloric orifice** lies in the transpyloric plane when the patient is recumbent, but wh patient is standing it falls to the level of the second or third lumbar vetebra, or lowe when any transient faintness or nausea causes loss of muscular tone (Barclay). The pyl slightly to the right of the midline in the empty stomach. As the stomach fills it de farther and moves a little farther to the right. The *lesser curvature* presents a definite no the junction of the cardiac and pyloric portions of the stomach—the *incisura angularis*.

greater curvature reaches the umbilical plane in the erect posture, even when the stomach is empty. When the viscus is full this curvature lies distinctly below this plane, being lower in women than in men (Hertz). The *pyloric portion* of the full stomach is directed backward and a little upward, as the distended pyloric vestibule moves further to the right than the pyloric orifice and lies on an anterior plane. In the recumbent posture the greater curvature lies above the umbilical plane, even when moderately distended, and the stomach is more obliquely placed. The *fundus* invariably contains gas, even when the stomach contains no food, in which case the organ forms a contracted J-shaped tube. In extreme distention the left dome of the diaphragm is so pushed up by the fundus that it lies at a level as high as or even higher than the right dome (Hertz). The pressure thus exerted on the heart accounts for the dyspnea and cardiac pain so often associated with flatulence. The position of the pyloric sphincter is shown on the outer surface by a very constant venous ring running toward both lesser and greater curvatures in the subserous layer at right angles to the long axis of the pyloric canal (Moynihan).

In connection with the extravasation of contents that results from perforating ulcers of the stomach, a knowledge of the subphrenic peritoneal fossæ is important (p. 1372). Perforation is rare on the posterior surface since it is less mobile than the anterior, and protective adhesions form readily. When it does occur, extravasaton into the omental bursa results, and such a perforation is exposed by turning up transverse colon and stomach and incising the transverse mesocolon. Perforation on the anterior surface usually gives rise to general peritonitis, but in the less serious cases an abscess may form localized to (1) the right subphrenic space, (2) the subhepatic fossa, or (3) the left subphrenic space, according to the situation of the ulcer on the stomach.

The spleen (fig. 1115; also figs. 632–636).—This lies very obliquely in the left hypochondrium, its long axis corresponds closely with the line of the tenth rib. It is placed opposite the ninth, tenth, and eleventh ribs externally, being separated from these by the diaphragm. Medially it extends behind the fundus of the stomach. Below, it overlaps slightly the lateral border of the left kidney. Its highest point is on a level with the spine of the ninth thoracic, and its lowest with that of the eleventh thoracic vertebra. Its upper pole is distant about 3.7 cm. (1½ in.) from the median plane of the body, and its lower pole about reaches the midaxillary line. (Godlee.) In the natural condition it cannot be felt; but if enlarged, its notched anterior margin extends downward toward the umbilicus, and is readily felt below the costal margin.

The pancreas (figs. 964, 965).—The head of the pancreas lies in the hollow formed by the three parts of the duodenum, on the bodies of the second and third lumbar vertebræ. The inferior vena cava lies behind it. The neck, body, and tail of the pancreas pass obliquely to the left and slightly upward, crossing respectively the commencement of the portal vein, the aorta, and the left kidney. The root of the transverse mesocolon is attached to the anterior margin of the gland, so that its anterior surface is related to the omental bursa, and its inferior surface to the greater sac. The importance of this relation in the formation of pancreatic pseudocysts has been referred to above.

Pancreatic ducts (fig. 964).—The main duct, the duct of Wirsung, opens into the common ampulla of Vater with the bile duct. This ampulla usually opens into the gut by a narrow orifice raised on a small papilla. A gall-stone impacted in the ampulla may cause a flow of bile backward along the duct of Wirsung, and so give rise to acute pancreatitis (Opie). The small accessory duct of Santorini opens into the duodenum independently about 2 cm. higher up. It often anastomoses with the larger duct in the substance of the gland.

A cyst originating in the pancreas may 'point' toward the anterior abdominal wall by three routes (which may also be used to reach the pancreas and to establish drainage): —(1 Above the stomach through the lesser omentum; (2) between stomach and transverse colon through the great omentum; (3) below the transverse colon through the transverse mesocolon. The posterior aspect of the head of the gland, with the third part of the common bile duct may be exposed by incising the peritoneum on the lateral margin of the second part of the duodenum, and turning the gut medially toward the middle line.

Small intestine.—The average length of the small intestine is about 6.85 m. (22½ ft.), though the length as measured *postmortem* varies considerably with the degree of contraction of the longitudinal muscular coat. The duodenum is about 25 cm. (10 in.) in length. Of the remaining portion the upper two-fifths constitute the jejunum and the lower three-fifths the ileum, though this division is quite arbitrary. Cases are recorded in which patients have survived the removal of over 5 m. (16 ft.) of small intestine.

The *first part* of the **duodenum** (fig. 965) extends from the pylorus on the first or second lumbar vertebra, backward and to the right. It ends near the upper pole of the right kidney and on the medial side of the neck of the gall-bladder, by turning down to form the less mobile *second part*, which descends in front of the hilum of the right kidney to the level of the third lumbar vertebra. The *third part* of the duodenum crosses the body of the third lumbar vertebra horizontally in the infracostal plane, and then turns up obliquely to the left side of the

spine and ends at the level of the upper border of the second lumbar vertebra in the duodenojejunal flexure. The first part is the most mobile, since it is covered back and front by peritoneum in the first half of its course. The second part has a peritoneal covering in front only and is devoid of it where it is crossed by the commencing transverse colon. The third part is covered by peritoneum in front except where the superior mesenteric vessels pass across it to join the commencement of the mesentery. It is probably the constricting effect of these vessels on the duodenum that gives rise to the acute dilatation of the stomach which occasionally follows abdominal operations.

The **duodenojejunal flexure**, which lies on the left side of the body of the second lumbar vertebra, immediately below the body of the pancreas, is held up to the right crus of the diaphragm by a band of fibromuscular tissue known as the *suspensory ligament of Treitz*. Some of the fibers of this structure are continued onward into the root of the mesentery. It is not found in pronograde animals. The duodenojejunal flexure is the commonest site of traumatic rupture of the small intestine, since it is the point of union of a fixed and a freely movable portion of the gut. The beginning of the jejunum turns downward and to the left (75 per cent) of cases) or to the right (25 per cent.). In the latter case, a mesocolic band and a single peritoneal fossa are found at the convexity of the angle. In the former case, there is no mesocolic band but two fossæ. The duodenal fossæ (see p. 1190) may give rise to retroperitoneal hernia and strangulation of the intestine.

In the operation of posterior gastroenterostomy, the duodenojejunal flexure is readily found by passing the hand along the under surface of the transverse mesocolon to the left side of the spine, the omentum and colon being turned upward. The first coil of the jejunum is anastomosed to the posterior wall of the stomach, which is exposed by making an opening in the transverse mesocolon.

Jejunum and ileum.—The **mesentery** contains between its two peritoneal layers the superior mesenteric vessels and their intestinal branches, the superior mesenteric plexus, lacteals and many lymph nodes on their course. These nodes are frequently enlarged in abdominal tuberculosis in children (*tabes mesenterica*). The attached border of the mesentery may be marked out on the surface by a line drawn from just below the transpyloric plane and a little to the left of the middle line (the duodenojejunal flexure), which curves downward and to the right to end in the iliac fossa at the junction of the intertubercular and right lateral vertical lines (the ileocecal valve).

Meckel's diverticulum which is present in about 2 per cent. of subjects (Treves) is found in the free border of the ileum 30 cm. to 1 m. (1 to 3 ft.) above the ileocecal valve. It is a remains of the vitellointestinal duct. It is usually a blind conical pouch some 6 to 9 cm. long with a free extremity, but may be attached to the umbilicus by a fibrous cord. This cord may cause acute intestinal obstruction by strangulating a coil of gut, or the diverticulum may be invaginated and form the starting-point of an intussusception.

The presence of **aggregated lymph nodules** (Peyer's patches) in the lower part of the ileum accounts for the fact that tuberculous ulcers and perforating typhoid ulcers are almost confined to this part of the gut.

Intestinal localization.—It often happens that the surgeon wishes to ascertain roughly to what part of the small intestine a given coil presenting in a wound belongs. The variations in length of the small intestine and the considerable range of movement of the coils during peristalsis render the problem difficult, but it may be stated as a general rule that the upper third of the intestine lies in the left hypochondrium and is not usually encountered in a wound; the middle third occupies the middle part of the abdomen, and the lower third lies in the pelvis and right iliac fossa (Monks) (see also p. 1194). The jejunum is thicker walled and more vascular than the ileum. The lumen steadily diminishes as we pass downward, hence foreign bodies such as gall-stones that pass through the jejunum are apt to become impacted in the lower ileum.

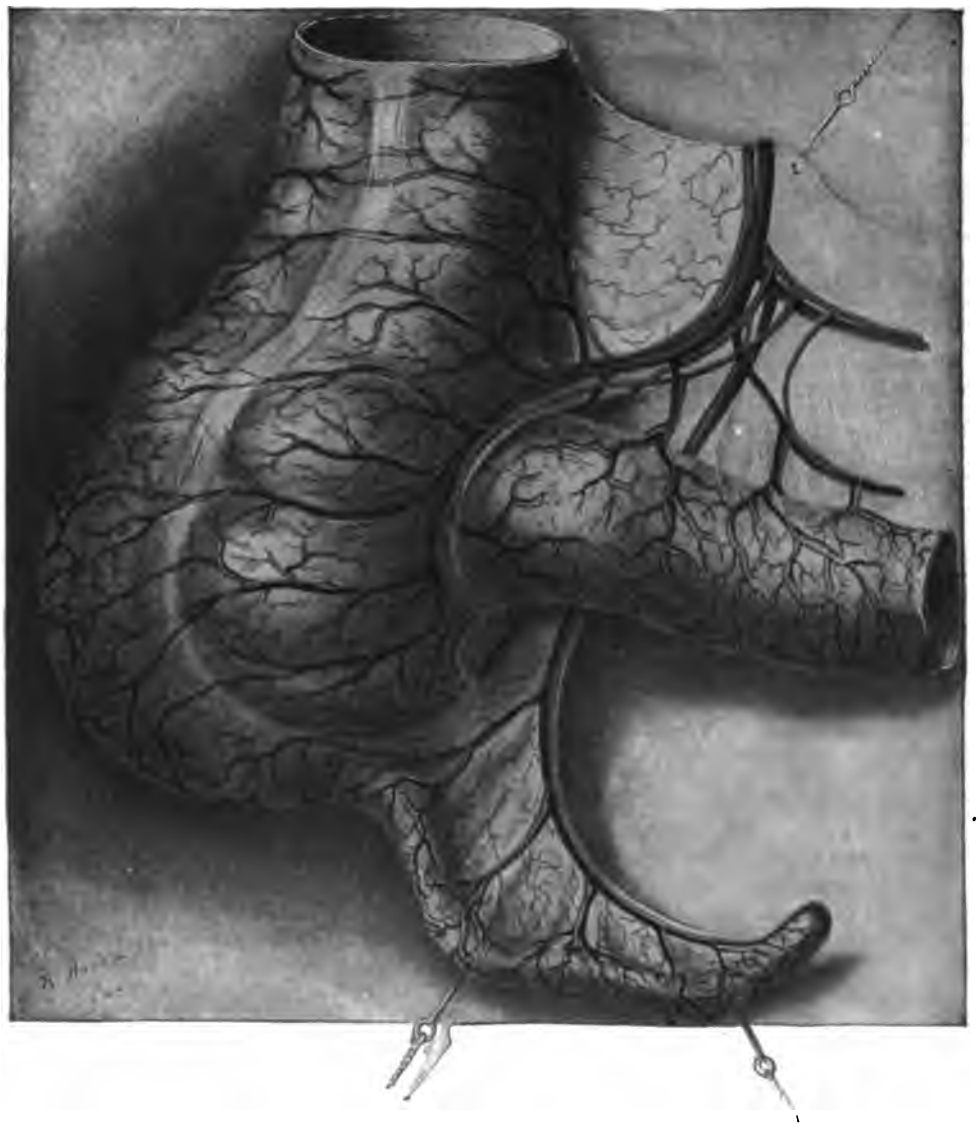
The most reliable indications of the level of a given coil are found, however, on inspection of the mesentery and its blood-vessels (see fig. 522) in Section VI). Opposite the upper part of the bowel the mesenteric arteries are arranged in a series of large primary anastomosing loops. From these the vasa recta run to the gut 3 to 5 cm. long, straight and unbranched. Passing downward toward the lower end, the single large primary loops give place to smaller and more numerous secondary loops arranged in layers coming nearer and nearer to the bowel. Hence the vasa recta become shorter. They become also less regular and more branched, and in the lower third of the small intestine are less than 1 cm. in length. The mesenteric fat in the upper third never reaches quite to the free edge of the mesentery, so that clear transparent spaces are left near the bowel. In the lower third the fat usually occupies the whole of the mesentery right up to the intestine, and makes it thicker and more opaque. (Monks: Trans. Amer. Surg. Assoc., 1913).

The average width of the mesentery, from its root at the posterior parietes to the bowel is 20 cm. (8 in.) and the longest part lies between 2 and 8 m. from the duodenum (Treves). The ileum is freely movable on a long mesentery down to the ileocecal region. In some cases however a congenital fusion of the left half of the mesentery with the parietal peritoneum near

the pelvic brim binds the bowel down a few inches above the ileocecal valve, and has been said to give rise to symptoms of intestinal stasis. (Flint, Gray, and Anderson.)

Large intestine. Ileocecal region.—The position of the ileocecal valve may be marked on the surface by the junction of the intertubercular and right lateral vertical lines, though it is often found considerably lower. It is situated on the posteromedial aspect of the cecum. The **cecum** (fig. 1096), which is the blind extremity of the colon lying below the horizontal level of the ileocecal valve, is approximately 6.2 cm. (2½ in.) in both vertical and transverse diameters, though

FIG. 1096.—BLOOD-VESSELS OF THE ILEOCECAL REGION. (Kelly). (See explanation of fig. 523.)



its size varies much with the degree of distention. It lies usually in contact with the anterior abdominal wall above the lateral half of the inguinal ligament (fig. 1095). The orifice of the appendix (vermiform process) lies some 2 cm. below the ileocecal valve. The cecum is completely covered by peritoneum as a rule, though exceptionally its posterior surface is bound down in the right iliac fossa.

The axial rotation of the midgut and descent of the cecum that normally take place during intrauterine life (p. 1173) are occasionally not completed, with the result that the cecum and appendix may be found above and to the left of the umbilicus, or less uncommonly just below the right lobe of the liver (3 per cent., Alglave), when an attack of appendicitis may simulate

inflammation of the gall-bladder. On the other hand certain cases occur in which the cec descends unusually far, proceeding downward and medially until it becomes a pelvic or whenever the bladder and rectum are empty. This pelvic position of the cæcum is foun 10 per cent. of infants (G. M. Smith, Anat. Record, vol. 5, 1911, p. 549).

In the commonest form of intussusception, the ileocecal valve and lower ileum are lapsed into the colon and carried down by the force of peristalsis toward the anus. The v in these cases forms the apex of the intussusceptum, however far it travels.

The **vermiform process** (**appendix**) (figs. 1095, 1096) is developed at apex of the cecum, and persistence of the apical appendix of fetal type, is uncommon. The fact that all three teniæ coli converge at the base of the app dix is an anatomical reminder of its primitive position. The anterior tenia i great service in operations on the appendix, since by following it down from colon the base of the appendix can always be found. The adult position of base of the appendix on the posteromedial aspect of the cecum is due to the proportionate growth of the lateral saccule of the cecum which comes to form apparent cecal apex.

The appendix averages 8 to 10 cm. (3.2–4 in.) in length in the adult. The position of its only is at all constant. It lies distinctly below McBurney's point, which is midway betwee umbilicus and the right anterior superior iliac spine. This point is often the seat of gre tenderness in appendicitis. The appendix itself may be found (1) pointing upward and t left toward the spleen, behind the terminal ileum and mesentery; (2) hanging over the p brim, in which position tenderness on rectal examination or pain on micturition results the organ is inflamed; (3) in the retrocolic fossa; and (4) with its tip projecting to the rig the cecum in the right lateral paracolic fossa, where it causes tenderness when inflamed to the anterior superior iliac spine. The course and to some extent the gravity of abs originating in the appendix will depend upon the position the inflamed organ is occupyi the time of perforation.

The **artery of the appendix** (fig. 1096) derived from the posterior branch of the ileo reaches it by running down behind the end of the ileum. It raises a fold of peritoneum e the *mesenteriolum* or *mesoappendix*. Very rarely the artery comes from the anterior bran the ileocolic.

The *teniæ coli* referred to above as converging on the base of the appendix contribut longitudinal *muscular coat*. The inner circular coat is thicker, but along the attachme the mesenteriolum certain gaps for the passage of lymph and blood-vessels occur in the mus coats. Through these gaps infection may easily spread from the mucosa to the perito (Lockwood).

The appendix is essentially a *lymph-gland* and has been called the 'abdominal to The lymph-follicles lie in the submucosa, fig. 953. They are poorly developed at birth reach their full development within the first few weeks of extrauterine life (Berry, Jour. A and Phys. vol. 35, 1900). Obliteration of the lumen is common but is usually inflammato origin, and not, as was once thought, a change normal in advanced age.

Pericecal fossæ.—In addition to the mesentery of the appendix certain other folds of toneum are usually present at the ileo-cecal junction: (1) the **ileocolic or anterior vasc** fold (fig. 1096) containing the anterior branch of the ileocolic artery; (2) the **ileocecal** bloodless fold of Treves, running from the lower border of ileum onto the cecum. The appe may be in a fossa behind either of these folds. It may also be found in the **retrocolic f** lying behind the cecum and commencement of ascending colon.

The **colon** (fig. 1095; cf. also figs. 944–948, 1020) is readily distinguished fr the small intestine by its three longitudinal teniæ and saccules (**haustra**) and the appendices epiploicæ, which are developed before birth.

The **ascending colon** (fig. 1095) runs with a slight lateral convexity upw from its junction with the cecum to the hepatic (right colic) flexure which under the ninth right costal cartilage at the level of the second lumbar verte and in contact with the anterior surface of the right kidney and the lower surf of the right lobe of the liver. It lies lateral to the right lateral vertical pl (linea semilunaris). This description is only true of an ascending colon exami by X-rays in the recumbent position. When the patient stands up, the flex may sink to the infracostal plane (third lumbar vertebra) or even lower. As colon ascends in the angle between the quadratus lumborum and psoas, it a passes backward at an angle of 51° with the horizontal, as may be seen in a sagi section through the right half of the abdo(men Coffey, Surg., Gyn and Ob 1912, 15: 390). The cecum and ascending colon are distended as a rule with fl contents and gas, and form the widest part of the colon.

The variations in the peritoneal attachments of the colon, which are of growing clin importance, are explained by its mode of development (p. 1174). During intrauterine after rotation of the midgut round an axis formed by the superior mesenteric vessels, ther a stage in which the colon has almost assumed its permanent position in the abdomen bu still provided with a free mesocolon for both ascending and descending parts. This represe the normal condition of quadruped mammals. In the normal human individual this stag

transient, and before birth the ascending and descending colons lose their mesenteries by fusion of the posterior layers with the parietal peritoneum. Meanwhile the great omentum, formed by a bulging out of the primitive dorsal mesogastrium, fuses with the transverse colon and its mesocolon. The extent of these processes of fusion varies, particularly as far as the ascending and descending colons are concerned. Thus only 52 per cent. of adults have neither ascending nor descending mesocolons (the normal condition). A mesocolon is found on the left side in 36 per cent. of all cases and on the right side in 26 per cent. (Treves). In only a small proportion (1.8 per cent.), however, does the true primitive type of ascending mesocolon persist, continuous with the mesentery of the small intestine (G. M. Smith). Such an anomaly renders the patient liable to volvulus of the ileocecal region. In the common types of incomplete fusion of its peritoneal attachments the colon is inadequately adapted to the upright position and is predisposed to ptosis. A layer of peritoneum sometimes found passing downward and medially from the parietes in the right flank onto the front of the ascending colon, known as Jackson's pericolic membrane, is probably due to persistence of an early stage in the development of the great omentum, which passes to the right across the ascending colon to join with the parietal peritoneum before the descent of the cæcum is complete, and so is the most primitive agent in fixing the proximal colon back in the right loin. This membrane is usually associated with a congenitally mobile ascending colon (Morley, Lancet, Dec. 1913).

At the **hepatic flexure** the colon bends forward and to the left, leaving the front of the kidney to which it is fixed, and crossing the second part of the duodenum. In the region of the flexure three inconstant peritoneal folds are met with giving it additional attachment to the neighboring parts, viz., (1) the *phrenocolic* and less commonly (2) the *hepatocolic* and (3) *cystocolic* ligaments (Testut). They must not be confused with pathological adhesions acquired after birth.

The **transverse colon** is freely mobile except at its extremities. It crosses the abdomen with a convexity downward and forward, being separated from the anterior abdominal wall in the middle region by the great omentum.

At the midline it usually lies near the umbilical plane in the recumbent posture, considerably lower in the erect, but may be found anywhere from the infracostal plane to the pubes, depending on the tonicity of the stomach. Its main artery, the middle colic branch of the superior mesenteric, must be avoided carefully in the operations of gastroenterostomy and gastrectomy, since ligature of this branch may cause gangrene of the transverse colon.

The left colic or **splenic flexure** lies far back in the left hypochondrium (figs. 1095, 1113) and is considerably higher than the hepatic flexure. It is in contact with the lower end of the spleen, and is almost invariably held firmly in position by its *phrenocolic ligament*, derived from the left extremity of the great omentum.

The **descending colon** is of narrower caliber than the preceding parts and usually is found firmly contracted and empty. It passes downward and forward in the angle between the psoas and quadratus lumborum and obliquely across to the right in the iliac fossa to end in the sigmoid (pelvic) colon. The lower part of the descending colon, from the iliac crest to the pelvic brim, is often termed the *iliac* colon.

In its upper part it lies in front of the convex lateral margin of the left kidney. The variations in its peritoneal attachments have been referred to above (p. 1378). The operation of lumbar colostomy, common in preantiseptic days, was performed through an incision in the back parallel with the last rib. The colon lies 2.5 cm. (1 in.) to the lateral side of the edge of the sacrospinalis, between the twelfth rib and iliac crest. The occurrence of a mesocolon here was a common source of difficulty in gaining access to the bowel without opening the peritoneum.

The **sigmoid colon** (pelvic colon or omega loop), is almost as long as the transverse colon, and forms a loop, the two ends of which, at the pelvic brim and at the front of the second (or third) sacral vertebra respectively, are placed somewhat closely together. The loop is thus anatomically predisposed to axial rotation, and is the commonest seat of volvulus in the whole intestinal tract.

On the left and inferior aspect of the pelvic mesocolon near its base, a small peritoneal fossa (*intersigmoid*) is usually found in the angle formed by the root of the mesocolon and the parietal peritoneum. It occasionally contains an internal hernia which may become strangulated.

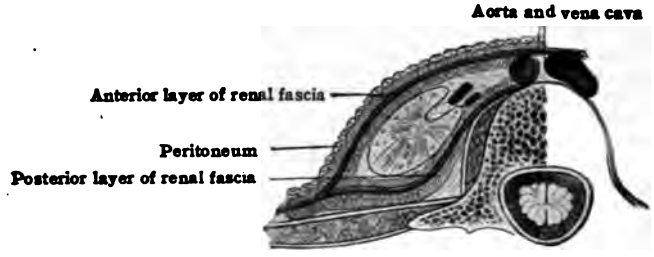
The upper part of the pelvic colon is frequently brought out and opened through an incision in the left iliac region to form an artificial anus in cases of inoperable growth of the rectum.

In advanced life, and in the chronically constipated, certain **diverticula** of mucous membrane are occasionally met with which project through the vascular gaps of the muscular coat into the bases of the appendices epiploicæ in this region, and also between the layers of the pelvic mesocolon (usually at the points where the vessels enter). They often contain fecal concretions and may become inflamed or even perforate, forming an abscess in the left iliac fossa. (McGrath: Surg., Gyn. and Obst., 1912, 15: 429.)

The junction of pelvic colon and rectum opposite the second (or third) sacral vertebra forms a more or less acute angle and constitutes the narrowest part of the colon. It is a frequent site of stricture.

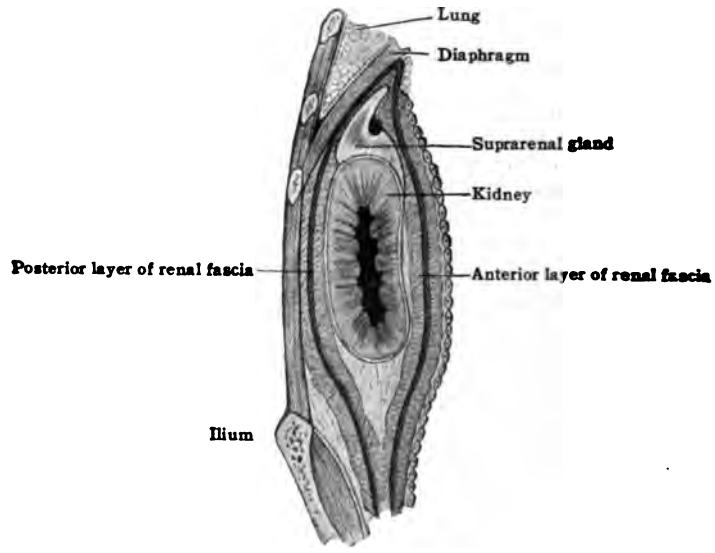
The kidneys.—These lie at the back of the abdominal cavity so deeply in hypochondriac and epigastric region as to be beyond palpation in most individu unless enlarged or unduly mobile (figs. 1020, 1099, 1113, 1115). The lo end of the right, being slightly lower than its fellow, encroaches in health upon lumbar and umbilical regions, and may be palpable on deep inspiration in sp subjects. These organs lie much higher and nearer to the vertebræ tha usually supposed to be the case, the upper two-thirds of the right and all the kidney being behind the ribs. Relatively to the vertebræ, the kidneys lie al the sides of the last thoracic and the first three lumbar.

FIG. 1097.—RENAL FASCIA, AS SEEN IN CROSS-SECTION.



To outline the kidneys from the front the following points should be noted: The u extremity of the right should reach as high up as the seventh costal cartilage, the left up t sixth, on either side close to the costochondral and interchondral junctions. This level correspond to one half way between the sternoxiphoid and transpyloric lines. The lower about 11 cm. (4½ in.) below this point, would be opposite to the subcostal line; that of right kidney is usually lower, and may encroach upon the umbilical line. For practical poses the hilus is opposite a point on the anterior abdominal wall, a finger's breadth media the tip of the ninth costal cartilage (Stiles), or the junction of the transpyloric and lat

FIG. 1098.—RENAL FASCIA, AS SEEN IN SAGITTAL SECTION.



vertical (or semilunar) lines. The importance of the relation of the last rib has been m tioned at p. 1275. The lateral vertical line has one-third of the kidney to its lateral side, a two-thirds to its medial side. The shortest distance between the two kidneys, obliqu placed as so to be closer above, 'at the upper part of their medial borders' (Thane and Godle measures about 6.2 cm. (2½ in.).

On the posterior surface of the body the kidney's boundaries are indicated by the followi —(1) A line parallel with, and 2.5 cm. (1 in.) from, the midline, between the lower edge of the of the spinous process of the eleventh thoracic and the lower edge of the spinous process of third lumbar vertebra; (2) and (3) lines drawn from the top and bottom of this line lateral at right angles to it, for 7 cm. (2¾ in.); (4) a line parallel to the first, and connecting the tremities of (2) and (3). Within this parallelogram the kidney lies (Morris).

The chief relations of the kidneys are:—posteriorly—quadratus lumboru psoas, diaphragm, last thoracic, iliohypogastric, and ilioinguinal nerves. T twelfth rib lies behind both, the right, as a rule, not reaching above the upp

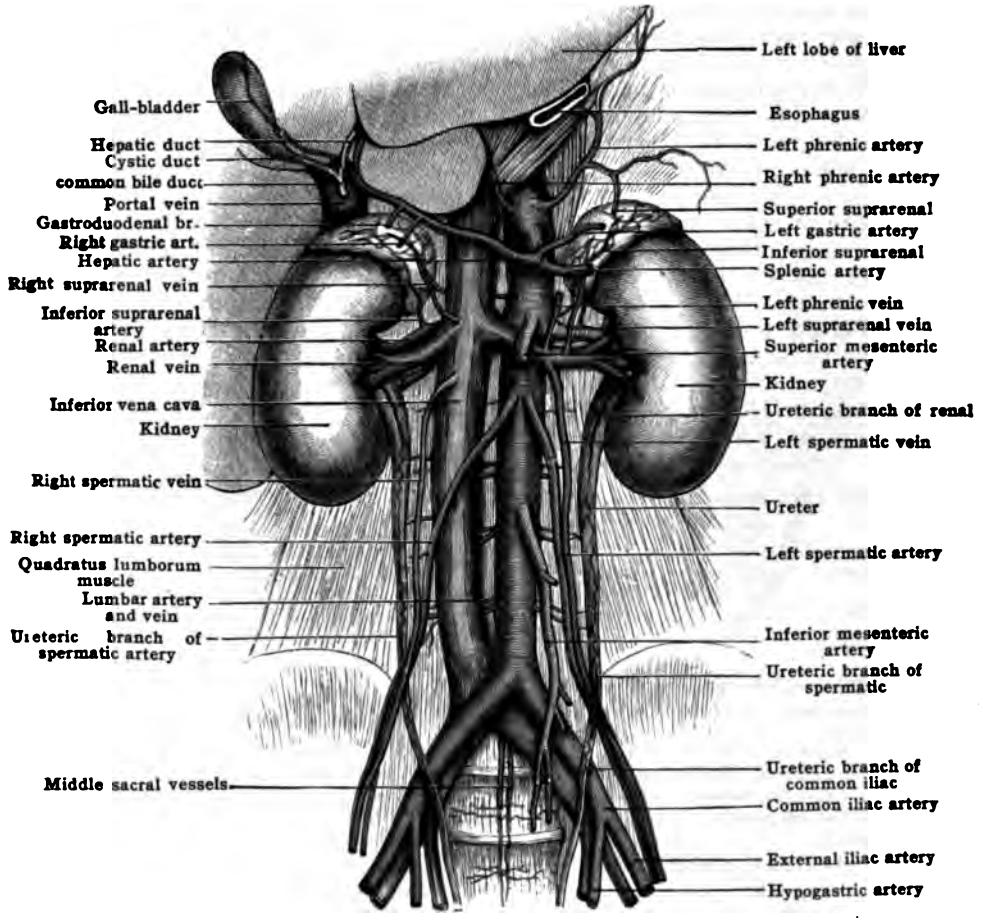
border. The left often reaches the eleventh rib. The pleural reflection usually crosses the twelfth rib obliquely reaching below its neck. **Anteriorly**—The liver, right colic flexure and second part of the duodenum (figs. 965 and 1020), on the right side. The liver, and stomach above, the body of the pancreas and spleen over the center, and the descending colon over the lower part of the left kidney.

The attachments of the specialized fibrous sheets known as the **renal fascia** are shown in figs. 1016, 1097 and 1098.

The anterior and posterior layers are seen to be continuous above and laterally. Medially and below they remain separate and it is in this direction that the abnormally movable kidney travels. The fatty tissue between the kidney and the renal fascia is known as the perinephric fat; that outside the fascia is the paranephric fat.

The kidneys are maintained in position by (1) the vascular pedicle: (2) fatty capsule and fascia: (3) above all by the intra-abdominal pressure.

FIG. 1099.—THE KIDNEYS, ABDOMINAL AORTA AND VENA CAVA INFERIOR.



Failure to ascend during development from its original position near the pelvic brim to its normal level accounts for certain cases of *movable kidney* of congenital origin. In these cases the renal artery may take origin from the common iliac artery. An *accessory renal artery* running into the lower end of the kidney from the aorta may cause kinking of the ureter and is a not uncommon cause of hydronephrosis.

Brödel has shown that incisions into the kidney should be made rather behind its convex border (Brödel's bloodless line). Occasionally fusion of the lower poles occurs during development across the middle line of the body, and a single *horseshoe-kidney* results, with double ureter and vascular supply.

The suprarenal glands (figs. 1064, 1099) are not so firmly attached to the kidneys as to the diaphragm: hence they are not encountered in operations for movable kidney and are not removed in nephrectomy.

The ureter (fig. 1099).—On an average 30 cm. (12 in.) long, this tube descends almost vertically in its abdominal course on the psoas muscle. It is crossed

obliquely by the internal spermatic or ovarian vessels. It crosses the brim of pelvis just in front of the bifurcation of the common iliac, and descends on side wall of the pelvis in front of the hypogastric artery.

The abdominal part of the ureter may be exposed extraperitoneally by an extension ward of the usual lumbar renal incision. It is found lying between peritoneum and p 3.7 cm. (1½ in.) from the middle line and when the peritoneum is stripped from the post abdominal wall the ureter is invariably carried with it. For further details and figures p. 1279.

Aorta and iliac arteries (figs. 570, 577).—The aorta enters the abdomen posite the last thoracic vertebra, a point 12 to 15 cm. (5 to 6 in.) above the bilicus, or rather above the midpoint between the infrasternal depression and umbilicus (Thane and Godlee), and thence, lying to the left of the midline, div into the two common iliacs opposite the disk between the third and fourth lun vertebræ, or opposite the body of the fourth lumbar vertebra. This poin about 2.5 cm. (1 in.) below and to the left of the umbilicus, and on a level wi line drawn across the highest part of the iliac crest. A line drawn from this pc with a slight curve laterally, to just medial to the center of Poupart's ligam will give the line of the iliac arteries; the upper third of this line giving the a age length of the common iliac. The relation of the common iliac veins is sh in fig. 1099. The **right,** much shorter than its fellow, lies at first behind and t somewhat lateral to its artery. The **left** is at first to the medial side of its art and then behind the right. At the upper part of the fifth lumbar vertebra bel and lateral to the right artery, the vena cava begins.

The site of some of the **branches of the aorta** may be thus approxima remembered as follows; The **celiac artery** is given off immediately after the a has perforated the diaphragm; directly below this is the **superior mesent artery.** About 2.5 cm. (1 in.) lower down, or 7.5 cm. (3 in.) above the umbili the **renal arteries** are given off. About 2.5 cm. (1 in.) above the umbilicus wo be the level of the **inferior mesenteric artery.** The relation of the above vessel the transpyloric line (p. 1183) is as follows: (Stiles.) The **celiac artery** is t fingers' breadth, the superior mesenteric one, above the line, the **renal arteries** a finger's breadth below it. The origin of the inferior mesenteric is midway tween the transpyloric and intertubercular lines.

THE PELVIS

The male pelvis will be considered first, then the female pelvis, and finall section on hernia.

The Male Pelvis

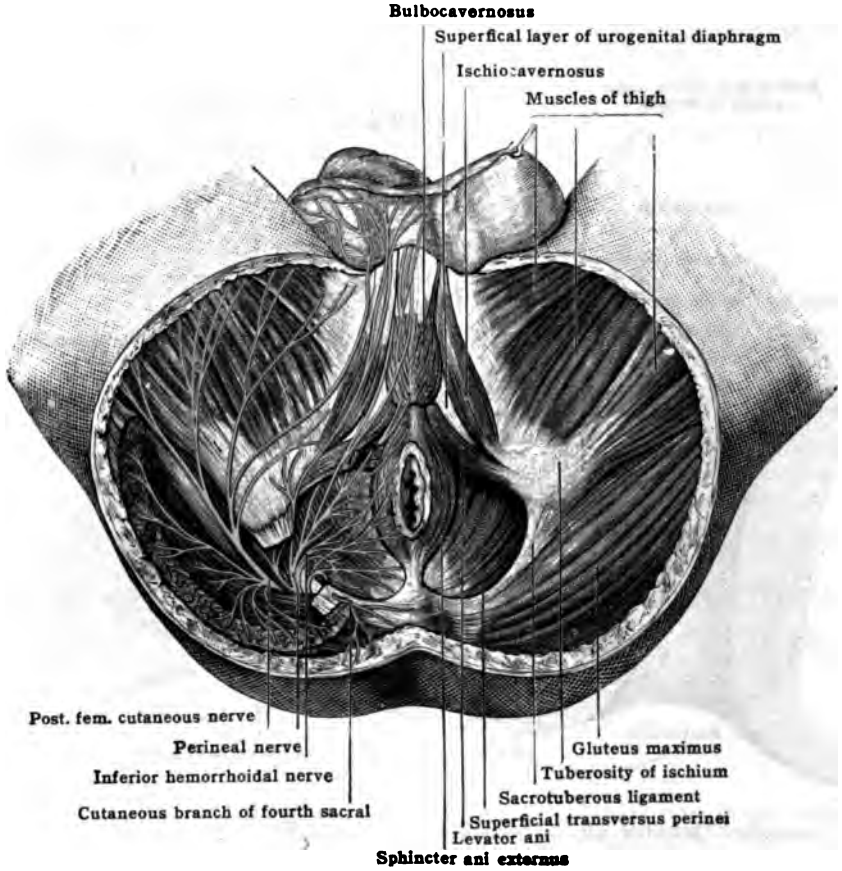
The topics under this heading will be considered in the following ord boundaries and subdivisions, scrotum and testis, ductus deferens and sperm

cord, penis and urethra, prostate, bladder, ischiorectal fossa, rectum and ana canal.

Bony boundaries.—These are the same in either sex (see p. 223). Above and in front is the symphysis pubis, rounded off by the subpubic ligament; diverging downward and laterally from this point on either side are the rami of the pubes and ischia, ending at the tuberosities of the latter. In the middle line behind is the apex of the coccyx, and reaching from this to the tuberosities are the sacrotuberous (great sacrosciatic) ligaments, to be felt by deep pressure, with the lower border of the gluteus maximus overlapping them.

The depth of the perineum varies greatly—from 5 to 7.5 cm. (2 to 3 in.) in the posterior and lateral part to 2.5 cm. (1 in.) or less in front. In the middle line, extending longitudinally through the perineum, is the raphe, the guide to the urethra, and 'the line of safety' (on account of the small size of the vessels here) for operations on it.

FIG. 1100.—THE MALE PERINEUM. (Modified from Hirschfeld and Leveillé.)



Subdivisions.—An imaginary line drawn transversely across the perineum from one tuber ischii to its fellow divides the lozenge-shaped space into **two triangles**—(1) An **anterior** or **urogenital**; and (2) a **posterior** or **anal** (rectal). The pelvic floor includes an upper or pelvic diaphragm (formed by the levator ani and coccygeus on each side) and a lower incomplete urogenital diaphragm.

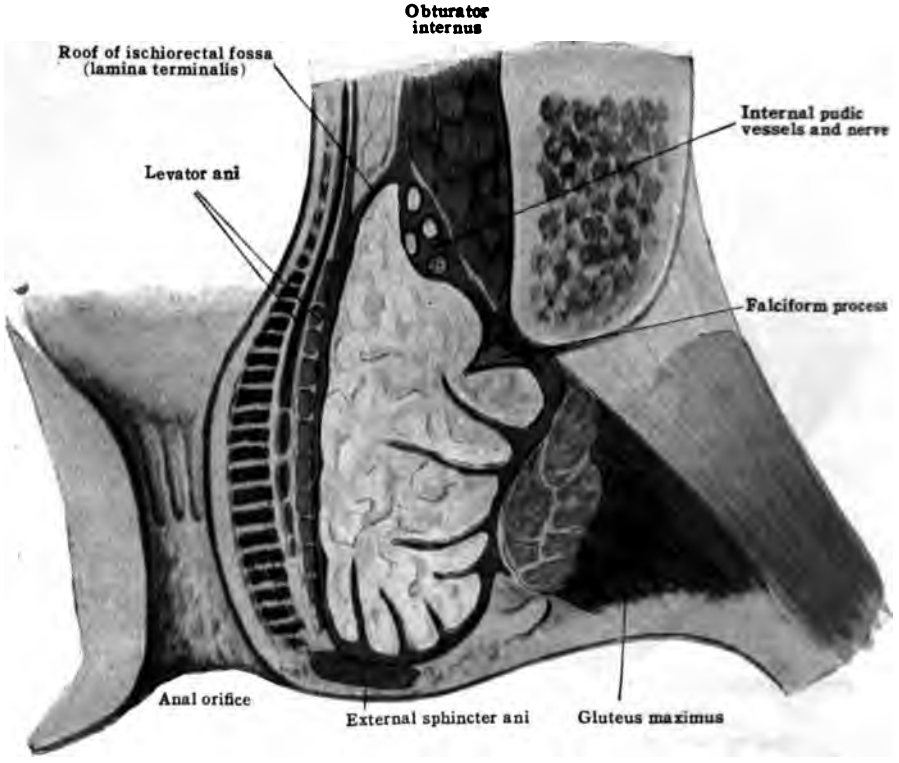
The **pelvic diaphragm** (figs. 1100–1102: see also figs. 428–431) is made up of the levator ani and coccygeus muscles. It is somewhat funnelshaped. When viewed from above or below (fig. 426), its fibers are seen to form horseshoe-like loops, arising on either side anteriorly, and passing posteriorly backward around the urogenital apertures to be inserted chiefly in the midline posteriorly. The pelvic diaphragm serves primarily for the support of the abdominal viscera. For a detailed description of these muscles, as well as those of the urogenital diaphragm and fasciæ, see section on the MUSCULAR SYSTEM.

The **urogenital diaphragm** (or trigone) (figs. 431, 1025, 1036), the lower dia-

phragm of the pelvic floor, is both morphologically and functionally differ from the upper. The urogenital diaphragm is a sphincter muscular layer. rived (with the sphincter ani externus) from the primitive *sphincter cloacæ*. T urogenital diaphragm is composed of superior and inferior fascial layers, enclos the membranous urethra, the sphincter urethræ membranaceæ and the tra versus perinei profundus. Superficial to the urogenital diaphragm is the sup ficial perineal interspace (fig. 431). This is covered by the superficial perin (Colles') fascia, and includes the crura and bulb of the corpora cavernosa, w associated muscles, vessels and nerves.

The space in the pelvic floor on each side below the pelvic diaphragm is ischiorectal fossa (figs. 430, 431, 1101). In the posterior or anal triangle, wh the urogenital diaphragm is absent, the ischiorectal fossæ form large wed shaped spaces. The *lower* wall or base is formed chiefly by the corresponding s and superficial fascia, and partly by the external sphincter ani; the *medial* w

FIG. 1101.—CORONAL SECTION OF THE ISCHIORECTAL FOSSA. (G. Elliot Smith.)



by the muscles (levator ani and coccygeus) and inferior fascia of the pelvic d phragm; the *lateral* wall by the obturator internus muscle, with the correspondi obturator fascia (with Alcock's canal, including the pudic vessels and nerve The *apex* of the fossa is above, where medial and lateral walls meet. The narr fibrous roof joining the medial and lateral walls just above the level of the inter pudic vessels and nerves has been called the *lamina terminalis* (Elliot Smi fig. 1101). Posteriorly the fossa is bounded by the gluteus maximus and l sacrotuberosum. Anteriorly on each side the ischiorectal fossæ extend as narr spaces between the pelvic diaphragm above, the urogenital diaphragm below, a the pelvic wall laterally (figs. 431–433).

Contents.—The ischiorectal fossa is filled with loose adipose tissue continuous with subcutaneous fat of the buttock. It is traversed by the inferior hemorrhoidal branches the internal pudic artery, with the associated veins and nerves, passing to the external a sphincter, the skin and the adjacent mucosa (fig. 1102). The superficial vessels and ner as they run forward to pierce the superficial perineal fascia, lie in this space, as well as inferior clunial (perforating cutaneous) branches and branches of the fourth sacral nerve. T inferior hemorrhoidal veins traverse the fossa obliquely from the lateral wall downward a medially. They are usually somewhat dilated near the anal orifice, and when morbidly

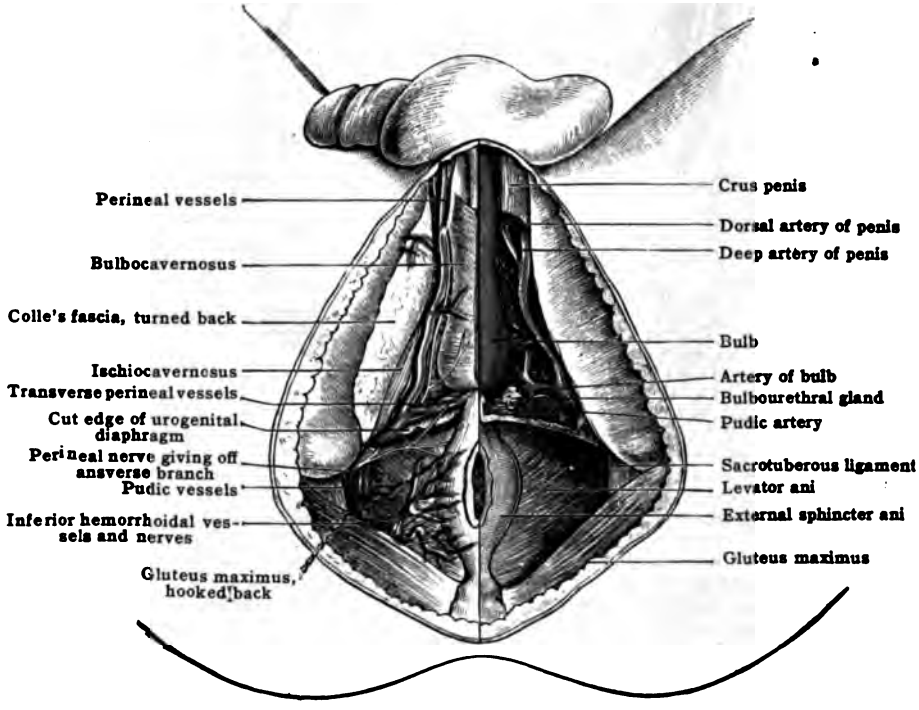
larged constitute the condition known as hemorrhoids ('piles'). The inner opening of an anal fistula caused by the bursting of an ischiorectal abscess into the gut is usually within 2 cm. of the anal margin, between the internal and external sphincters. Or (more frequently) these fistulas are subcutaneous, the opening into the bowel being external to the external sphincter.

The **central point of the perineum** (figs. 1100, 1102, 1103) is in the adult nearly an inch (2.5 cm.) in front of the anus, or midway between the center of the anus and root of the scrotum. Here the following structures meet, viz., the levatores ani, the two transverse perineal muscles, the bulbocavernosus, and the sphincter ani.

The comparative weakness of the attachment of the sphincter ani in front, i. e., not into a bony point, is important in the division of it, as in operation for fistula. The sphincter should never be cut through anteriorly, especially in women, where its attachment here, blending with the sphincter vaginæ, is very weak. This point also corresponds to the center of the lower

FIG. 1102.—THE ARTERIES OF THE PERINEUM.

On the right side of the perineum (left side of fig. 1102) Colles's fascia has been turned back to show the superficial vessels. On the left side the superficial vessels have been cut away with the anterior layer of the urogenital diaphragm to show the deep vessels.



margin or base of the urogenital diaphragm (triangular ligament). Its development varies much in different bodies. A little in front of this point is the bulb, with the corpus spongiosum passing forward from it. This would also be the level of the artery of the bulb, so that in lithotomy the incision should always begin below this point. A knife introduced at the central point, and carried backward and very slightly upward, should enter the membranous urethra just in front of the prostate, e. g., in median lithotomy and Cock's external urethrotomy. If pushed more deeply, it would enter the neck of the bladder.

In median lithotomy, an incision 3.7 cm. (1½ in.) long is made through the central tendinous point and raphe, so as to hit the membranous urethra. The following structures are divided:—Skin and fasciæ; some of the most anterior fibers of the external sphincter ani; raphe and central tendinous point; minute branches of transverse perineal vessels and nerves; base of urogenital diaphragm in center; membranous urethra and constrictor urethræ.

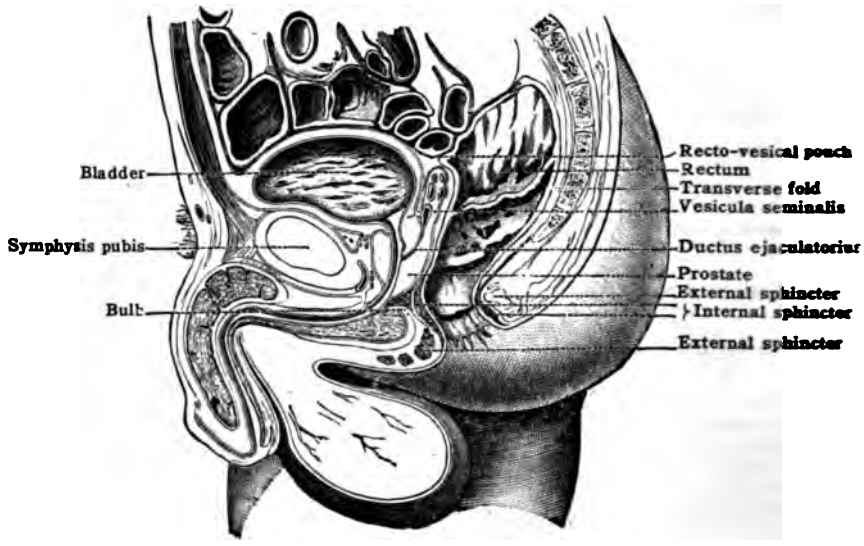
The attachments and arrangements of the **superficial fascia** (fig. 1102) must be traced and remembered. Of the two layers of which it consists, the superficial alone extends over both urogenital and anal triangles alike, and is continuous with the similar structures in adjacent regions, the only difference being that, if traced forward into the scrotum and penis, it loses its fat, and contains dartos fibers. The deeper layer, found only over the urogenital triangle, is called the fascia of Colles. Attached at the sides to the rami of the pubes, behind to the base

of the urogenital diaphragm, and open in front, it forms the superficial wall of a somewhat triangular pouch (*superficial perineal interspace*), containing the superficial vessels, nerves, and muscles, the bulb, adjacent part of the urethra, and crura of the penis. Owing to this space being closed behind and open in front, urine or other fluids extravasated within this space will obviously tend to make their way forward into the scrotum, penis, and lower part of the abdominal wall.

More deeply located, **between the two layers of fascia of the urogenital diaphragm,** are—(1) The membranous urethra; (2) deep transverse perineal muscle and sphincter of the membranous urethra; (3) the bulbourethral (Cowper's) gland; (4) and (5) part of the pudic artery and nerve, and branches.

The scrotum.—The skin of the scrotum is thin and delicate so that when distended, as by a hydrocele in the tunica vaginalis, it is remarkably translucent. Attached to its deep aspect is a layer of involuntary muscle, the dartos. When the dartos is contracted, as under the influence of cold, the scrotal skin becomes rugose.

FIG. 1103.—SAGITTAL SECTION OF MALE PELVIS (× 1/3). (Braune.)



To this tendency to wrinkling, with consequent irritation from retained dirt, and the presence of many sweat glands the frequency of epithelioma in this part is due. The dartos is apt to cause inversion of the skin in wounds of the scrotum, but this difficulty in suturing may be counteracted by the application of a hot sponge, which relaxes the muscle.

The **superficial fascia** of the scrotum is continuous with the fascia of Colles and the superficial fascia of the penis. Hence extravasation of urine under the fascia of Colles's balloons the scrotum and penis. The laxity of the areolar tissue under the dartos accounts for the great swelling that occurs in edema of this part.

The lymphatics of the scrotum, important by reason of the extension of scrotal cancer, drain into the superficial inguinal nodes. Those from the anterior aspect nearest the median raphé run to the superolateral glands of this group, within a few cm. of the anterior superior spine. (Morley: Lancet, 1911 (ii), p. 1545.)

The numerous large sebaceous glands that are found in the skin of the scrotum may give rise to cysts or adenomata. The deeper layers of the scrotum are derived from the abdominal wall, being brought down by the processus vaginalis in the descent of the testis.

Testis and epididymis.—The left testis, the first to descend, lies somewhat lower in the scrotum, and this fact is one reason for the frequency with which a varicose condition of the spermatic veins occurs on the left side. On *palpation* the smooth firm body of the testis, pressure on which causes the characteristic 'testicular sensation' can be felt to lie in front of and rather medially to the epididymis. The three parts of the latter, the *caput* above, the *body*, and the *cauda epididymidis* below, can also be distinguished. Running upward from the back of the epididymis to the subcutaneous inguinal ring the spermatic cord can

be felt. The bulk of the cord is made up of its coverings, of which the cremaster muscle is the most considerable, and of the pampiniform plexus of veins. On rolling the cord between the finger and thumb the **ductus deferens** can be felt like a piece of whipcord in the posterior part.

The *ductus (vas) deferens* is thickened and nodular in tuberculous epididymitis. The nodule which is so characteristic of tuberculous epididymitis develops in by far the greater majority of cases in the tail of the epididymis. In varicocele the dilated and elongated veins of the pampiniform plexus feel on palpation like a bag of worms in the scrotum. It is important that the student, before studying diseased conditions, should make himself familiar with the feel of the normal parts as mentioned above and be able to identify them. Dissection made with the view of removing the epididymis should be made from the lateral side, so that when the spermatic artery is approached the epididymis has been practically freed.

Underneath the visceral layer of the tunica vaginalis, the body of the testis is covered by a dense fibrous layer, the *tunica albuginea*, which accounts for the small extent of swelling in orchitis as compared with epididymitis. The *lymphatics* of the testis run up in the spermatic cord through the inguinal canal, and accompanying the spermatic vessels end in the lumbar lymph nodes, below the level of the renal arteries. These nodes may be reached and removed along with the vessels by making an incision in the loin above the inguinal (Poupart's) ligament, and stripping the peritoneum off the posterior abdominal wall.

The **epididymis** is the convoluted first part of the duct of the testis, about 6 m. (20 feet) in length. Its three portions are in differing connection with the testis. Thus the *cauda* is held in place by connective tissue, the *body* by the same medium; the *caput* by the vasa efferentia. Thus, when tubercular disease begins here, the testis itself is more likely to be early involved.

Ductus deferens.—The two extremities and the course of this involve several practical points. About 45 cm. (18 in.) long, it begins, convoluted at first and with a distinct bend upward, in the cauda epididymidis. It thence passes almost vertically upward at the back of the testis and cord to the tubercle of the pubes. Entering the canal, it lies on the grooved upper aspect of the inguinal (Poupart's) ligament, and then under the arching fibers of the internal oblique and transversus, upon the transversalis fascia. Its position, characteristic feel, and yellowish aspect are well-known guides in operations for varicocele and hernia, while it is always to be isolated and palpated when tubercular disease below is suspected. Leaving the canal by the abdominal inguinal ring, it hooks round the inferior epigastric artery and then descends into the pelvis over the external iliac vessels. Continuing its course downward and backward over the side of the pelvis, it arches backward over the side of the bladder (fig. 950), superficial to the obliterated hypogastric artery, and then deep to the ureter. The two ducts now help to form the lateral boundaries of the external trigone, between the base of the bladder and the rectum. They here become dilated [ampulla ductus deferentis] and then contract to empty into the ejaculatory ducts (see figs. 1025, 1030–1032).

The **vesiculæ seminales** are diverticula growing out from the lower end of the deferential ducts at an acute angle, one on each side. They lie below and lateral to the deferential ducts and are related in front to the base of the bladder and posterior surface of the prostate, behind to the rectum, and above to the rectovesical pouch of peritoneum, which also descends to cover the upper part of their posterior aspect. The normal vesiculæ seminales can scarcely be distinguished from the base of the bladder on rectal palpation, but when diseased, as in tuberculous or gonorrheal vesiculitis, are enlarged and indurated and can be detected readily.

The **ejaculatory ducts,** formed by the union of the vesicular and deferential duct of each side, are 2–2.5 cm. in length. The first few millimeters of their course is extraprostatic, and then entering the posterior surface of the prostate they run side by side downward and forward through the gland, close to the middle line, to open into the urethra on the colliculus seminalis at either side of the opening of the prostatic sinus. It is by these little ducts that infection travels from the urethra to the vesiculæ and epididymis in gonorrhea.

Descent of the testis.—The testis is developed between the tenth and twelfth thoracic segments of the embryo (see p. 53), and subsequently moves downward. By the third month of intrauterine life it descends into the iliac fossa; from the fourth to the seventh month it lies at the abdominal inguinal ring; during the seventh month it passes obliquely through the abdominal wall by the inguinal canal; by the eighth month it lies at the subcutaneous inguinal ring, and it reaches the fundus of the scrotum about the time of birth. The left testis is slightly earlier than the right in all these stages. The descent referred to is due in part to the common descent of organs, associated with the descent of the diaphragm, but mainly to the **gubernaculum.** This is a mass of fibromuscular tissue that forms under the *inguinal fold* (or *plica gubernatrix*) of peritoneum below the testis as it lies in the iliac fossa, and in the mesorchium. It grows down obliquely through the abdominal wall from a point lateral to the inferior epigastric artery, and tunnels out a passage for the testis. As it travels down into the scrotum it carries in front of it three layers of investing fascia derived from the abdominal wall, viz., external spermatic fascia from the external oblique, cremasteric from internal oblique and transversus muscles, and infundibuliform fascia from the transversalis fascia. The gubernaculum is attached above to the peritoneum and the posterior aspect of the testis, and by its subsequent contraction it draws down into the scrotum first a diverticulum of peritoneum, the **processus vaginalis,** and secondly the testis, which projects into the processus from behind just as it did into the celom.

Shortly after birth, obliteration of the processus vaginalis should occur, commencing at the deep abdominal ring and immediately above the testis. The part of the processus between these two points disappears completely. The lowest part, surrounding the testis, persists as the tunica vaginalis. Failure of obliteration, if complete, leaves a *congenital hernial sac;* if only the upper part persists, and does not communicate with the tunica vaginalis, it is called a

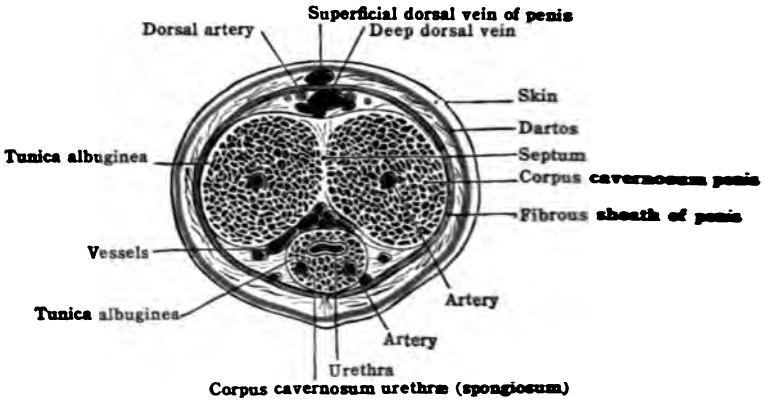
funicular sac. Cysts originating in the processus vaginalis between the upper and lo points of primary occlusion are known as *encysted hydrocele of the cord.*

Undescended testis.—It occasionally happens that descent of the testis fails on one both sides, and in these cases the organ may remain, (1) in the iliac fossa, (2) in the ingu canal, or (3) at the subcutaneous ring. Deprived of the protection normally afforded aga injury by the scrotum and tunica vaginalis, the misplaced testis is subject to trauma, sho tendency to torsion of its pedicle owing to its long mesorchium, and sometimes becomes seat of malignant disease. A funicular hernial sac is generally present. Such testes are a phic and functionally deficient, and it is probably owing to their small size at an early stage the gubernaculum fails to gain a hold on them. It has been shown by Bevan (Jour. A.M 1903, 41 : 718) that in undescended testis the ductus deferens is usually long enough to allow organ to be placed in the bottom of the scrotum by the surgeon without tension provided the spermatic artery and pampiniform plexus of veins are divided. The blood-supply of organ is then entirely derived from the deferential artery, a branch of the superior vesical. rare cases the testis descends in a wrong direction (ectopia testis) and comes to lie in the perine over Scarpa's triangle, or on the pubes.

Penis (figs. 1102–1104).—The subcutaneous tissue of the penis, as of scrotum, is devoid of fat and the delicate skin is very mobile and distensible, he the ballooning of these parts in extravasation of urine or edema. The fa penis is continuous with Colles's fascia.

In radical amputation of the penis for malignant disease the whole organ, including crura, is removed through an incision that splits the scrotum, and the stump of the co spongiosum (corpus cavernosum urethræ) is brought out into the perineum behind the scro

FIG. 1104.—CROSS-SECTION OF PENIS.



The preputial orifice varies greatly in size. Normally large enough to allow easy re tion of the prepuce from off the glans, it is frequently so small that retraction is impos and it may even cause difficulty in micturition. The mobility of the skin over the penis be borne in mind in the operation of circumcision, and care taken lest too much of the pre be removed, leaving insufficient skin to cover the penis. In this operation the vessels which bleeding occurs lie, (1) on the dorsum, (2) in the frenum.

Congenital malformations of penis.—At an early stage of development (see p. 52 the thra opens on the inferior aspect of the penis behind the glans. After the ingrowth of epithel that forms the glandular urethra, this primitive meatus should close. Occasionally, however persists, and the glandular urethra is represented by a groove on the under aspect of the gl In these cases of *hypospadias* the glans is flexed on the penis and the prepuce is deficient be and has a peculiar 'hooded' appearance. In *epispadias* the upper wall of the urethra corresponding part of the corpora cavernosa are absent. This condition is usually pre in cases of ectopia vesicæ.

The **male urethra** (figs. 1025, 1037) is about 20 cm. (8 in.) in length, consist of the **cavernous** portion, 16 cm. ($6\frac{1}{2}$ in.), **membranous** 1 cm. ($\frac{2}{5}$ in.) and pr **tatic** 3 cm. ($1\frac{1}{4}$ in.). The narrowest part is the external orifice, and next to it membranous urethra. The prostatic urethra is the widest and most dilatab The bulbous urethra, just in front of the urogenital diaphragm, is wider than rest of the penile portion, but since it forms the most dependent spot in fixed part of the urethra from bladder to suspensory ligament of penis, it specially prone to gonorrheal stricture. Behind the bulb, the urethra curv suddenly as it passes through the urogenital diaphragm and contractile of sphincters of the membranous urethra may here give additional difficulty in passage of a catheter.

False passages most commonly occur just outside the floor of the bulb on account of the ease in entering the membranous urethra. The point of a small catheter may also be cau

in the following apertures: (1) The lacuna magna in the roof of the fossa navicularis of the glandular urethra; (2) other crypts or lacunæ in the penile part, mostly situated in the upper wall; (3) the prostatic sinus in the floor of the prostatic urethra about its center. With the penis raised the urethra presents a simple curve under the symphysis with the proportions of an ordinary silver catheter.

It is in the region of the urogenital diaphragm that the urethra is most liable to be damaged by a fall or blow, and the urine extravasated as a result will be beneath Colles's fascia. In rupture of the membranous urethra urine may find its way in front of the inferior fascia of the urogenital diaphragm by coexisting injury to this, or through openings in the vessels, etc.; in a few such cases urine will make its way backward behind the fascia into the space of Retzius, ascending thence between the peritoneum and transversalis fascia. The attachment of the deep layer of superficial fascia to the base of the urogenital diaphragm accounts for the fact that urine extravasated from a ruptured urethra or through an opening behind a stricture passes not backward into the anal triangle, but forward onto the scrotum and abdominal wall.

The **prostate** (figs. 1025, 1103) consists of a mass of racemose glandular tubules imbedded in a fibromuscular stroma, that surrounds the first part of the urethra and lies below the neck of the bladder. Its **base** is intimately connected with the bladder by the continuation of vesical and urethral mucous membrane and by the insertion of the outer longitudinal muscular coat of the bladder into the gland.

The inner circular muscle fibers of the bladder become specialized round the internal urethral orifice to form the *internal sphincter*. Adenomatous enlargements of the gland usually grow upward through this sphincter which is thus dilated and pushed aside, so that the glandular growth is covered only by vesical mucous membrane.

The **apex** of the prostate lies at the level of the lower border of the pubic symphysis and 1.5 cm. behind it. It is firmly fixed to the superior fascia of the urogenital diaphragm (deep layer of the triangular ligament) and here the urethra leaves it to become the membranous part. The **anterior surface** directed vertically lies 2 cm. behind the lower part of the pubic symphysis in relation to the prostatic plexus of veins: and from it the dense puboprostatic ligaments run forward on either side to the pubes. The **posterior surface** is in contact with the rectum, through the anterior wall of which it may be palpated 4 cm. (1½ in.) above the anal margin. It is separated from the rectum by the two layers of the rectovesical septum (Elliot Smith, Jour. Anat. and Physiol., vol. 42, 1908). The **lateral surfaces** are supported by the anterior fibers of the levator ani, from which, however, they are separated on each side by a dense mass of fibrous tissue in which the pudendal (prostatic) plexus of veins is imbedded.

The *prostatic urethra* traverses the gland nearer the anterior than the posterior surface, with a slight forward concavity. Its floor is placed posteriorly and presents an eminence, the *colliculus seminalis*, about the center of which is the orifice of the prostatic sinus, on either side of which open the common ejaculatory ducts. The prostate is indefinitely divided into two lateral lobes. The fissure uniting them across the middle line in front of the urethra (the anterior commissure) is fibromuscular and contains no glandular tissue. Behind the urethra the lateral lobes are continuous and the portion of gland lying between bladder, ejaculatory ducts and urethra has been erroneously termed the 'middle lobe.' Though not a separate lobe anatomically, adenomatous hypertrophy of this part is common, when it projects up into the bladder, and prevents the proper emptying of that organ.

Capsule and sheath of the prostate.—In senile enlargement of the prostate removal may be effected by the *suprapubic* or by the *perineal* route. In the former, the bladder is opened above the pubes, the mucous membrane lying over the gland as it projects into the bladder is scratched through and with the finger the whole adenomatous mass is enucleated. This process usually involves tearing out the whole of the prostatic urethra, and the ejaculatory ducts. The parts left behind consist of (1) the **'capsule'** which is simply the outer part of the gland proper stretched over the adenomatous mass, and consists of fibromuscular tissue with a few flattened glandular tubules (C. Wallace). Outside this (2) the fibrous 'sheath' is derived from the visceral layer of pelvic fascia, in which is imbedded, on the anterior and lateral aspects of the gland, the prostatic plexus. Since these veins are not torn there is comparatively little hemorrhage. In the *perineal* operation the posterior surface of the gland is exposed by cutting through the perineum between the bulb and external sphincter ani, and dividing the attachment of the rectourethral muscle to the urogenital diaphragm and its inferior fascia. This exposes the back of the rectovesical septum (aponeurosis of Denonvilliers) which is split at its base, opening up the rectoprostatic space of Proust. By a longitudinal incision into the prostate on each side the adenomatous lateral lobes may be enucleated separately, and it is claimed without injury to the urethra or ejaculatory ducts (Hugh Young, J. H. Hosp. Rep., vol. 14, 1906.

The **urinary bladder** (fig. 1103) lies above the pubic symphysis at birth and so is mainly an abdominal organ. The *anterior surface*, in contact with the abdominal wall, has no peritoneal covering, but posteriorly the peritoneal reflection descends to cover the posterior surface of the prostate, which is relatively lower

than in the adult. The adult bladder when empty forms
organ behind the symphysis, and bounding the retropu
posteriorly.

that pierce the muscular coat about the level of the inferior transve
toneal reflection. Joining the submucous layer, these arteries run d
to the anal canal, where they anastomose with (2) the **middle hemor**
of the hypogastric (internal iliac) and (3) the **inferior hemorrhoidal**

pudendal. The veins correspond. Their free anastomosis in the **hemorrhoidal plexus** under the rectal columns, the union afforded here between the portal and systemic veins, the absence of valves in the superior hemorrhoidal veins, and the constriction they are subject to in passing through the muscular coat, are some of the anatomical causes of the frequency of hemorrhoids.

The branches of the superior hemorrhoidal artery to the rectum anastomose but little with one another, as compared with the sigmoid arteries to the pelvic colon. The main trunk of the superior hemorrhoidal usually receives a large anastomotic branch from the lowest sigmoid artery 1–2 cm. below the sacral promontory, upon which the upper part of the rectum is dependent for its blood-supply after ligature of the superior hemorrhoidal. Hence in high excision of the rectum it is important to place the ligature on the superior hemorrhoidal above the sacral promontory if sloughing of the gut is to be avoided. (Hartmann, Ann Surg., Dec., 1909.)

For lymphatics of the rectum see p. 769).

Supports of the rectum.—The anal canal is fixed by its attachment to the levator ani and perineal body. After division of the perineal body and rectourethral muscle in front, the rectum is readily separable from the back of the prostate and rectovesical septum. When the levator ani has been divided on each side and the peritoneum opened, as in the perineal operation for excision of the rectum, the gut cannot be pulled down freely. The hand passed up behind it in the hollow of the sacrum meets on each side with a dense fibrous layer running from the sacrum opposite the third foramen onto the side of the rectum. This is the *rectal stalk* (Elliot Smith) and consists of dense fibrous tissue round the nervi erigentes from second, third and fourth sacral foramina and the middle hemorrhoidal vessels. It lies about 2.5 cm. above the levator ani, and after division of it the bowel is easily freed, so that the whole of the rectum and part of the pelvic colon may be drawn out at the perineum without tension.

Rectal examination.—The following points can be made out by the finger introduced into the male rectum (cf. fig. 1025):—(1) The thickened, roll-like feel of a contracted external sphincter; (2) the thinner, more expanded, internal sphincter extending upward for 2.5 cm. (1 in.) from this; (3) the rectal insertion of the levatores ani, which here narrows somewhat the lumen of the gut; (4) above the anal canal, with its contrasting capaciousness, is the more or less dilated ampulla of the rectum proper; (5) the condition of the ischiorectal fossæ on either side; (6) the membranous urethra in front, especially if a staff has been introduced; the instrument now occupies the middle line, and has the normal amount of tissue between it and the finger, thus differing from one in a false passage (in a child an instrument is especially distinct); (7) just beyond the sphincters, or 3.7 cm. (1½ in.) within the anus, lies the prostate; (8) converging toward the base of the prostate, and forming the sides of the triangular space, are the vesiculæ seminales and ejaculatory ducts. These can rarely be felt unless diseased and enlarged; any enlargement of the sacculated ends of the deferential ducts is much more perceptible; (9) it is within this triangular space that the elasticity of a distended bladder can be felt. (10) Usually the lowest of the transverse folds (folds of Houston), semilunar in form and about 1.2 cm. (½ in.) in width, can be made out (fig. 1103). (11) Behind, the coccyx and its degree of pliability and the lower part of the sacrum. It may also be possible to feel enlarged sacral nodes and a growth from the other pelvic bones.

The following relations are found by **rectal examination in the female** (cf. figs. 1046, 1048): Anteriorly, the soft perineal body and rectovaginal septum will be met with, and, through the latter, the cervix and external orifice (os uteri), and, higher up, the lower part of the cervix uteri. More laterally the ovaries may be felt, but the uterine or Fallopian tubes, unless enlarged and thickened, are not to be made out. The student should be familiar with the feel of a healthy rectouterine or rectovesical pouch, according to the sex, and the coils of intestine which it may contain, so as to be able to contrast this with any collection of inflammatory or other fluid or mischief descending from the upper pelvis, e. g., from the vermiform appendix. Posteriorly, certain structures are met with in either sex. After a very short interval (sphincter and anococcygeal body) the finger reaches the tip of the coccyx and explores the hollow of the sacrum. On each side are the ischial tuberosity and wall of the true pelvis. The finger hooked lateralward and upward, comes on the border of the falciform process of the sacrotuberous (great sacrosciatic) ligament, passing between the above-mentioned bones.

FEMALE GENITAL ORGANS

The external organs will be considered first, followed by the internal. Under the external organs are included, for convenience, the labia majora and minora at the sides; and, in the middle line, from above downward—(1) The glans clitoridis with its prepuce; (2) the vestibule; (3) the urethral orifice; (4) the vaginal orifice with the hymen or its remains; (5) the fossa navicularis; (6) the fourchette; (7) the skin over the base of the perineal body.

These parts have been described elsewhere, and only those points which are of importance in a clinical examination will be alluded to here.

The **labia majora** (fig. 1049) are two thick folds of skin, covered with hair on their outer surface, especially above, where they unite (*anterior commissure*) in the mons Veneris. They contain fat, vessels, and dartos, but become rapidly thinner below, where they are continuous at the front of the perineum (their *posterior commissure*). When the above folds are drawn aside, the **labia minora,** or **nymphæ,** appear, not projecting, in a healthy adult, beyond the labia majora. They are small folds of skin, which meet anteriorly in the prepuce of the clitoris,

and posteriorly blend with the labia majora about their center. Sometime especially in nulliparæ, they unite posteriorly to form a slight fold, the fourchett The **glans clitoridis,** covered by its prepuce, occupies the midline anteriorl

Behind it comes the **vestibule,** a triangular smooth surface of mucous mem brane, bounded laterally by the labia minora. In the midline of the vestibu about 12 mm. (½ in.) behind the glans clitoridis and 25 mm. (1 in.) in front of tl fourchette, is the meatus or opening of the urethra (figs. 1046, 1049).

The **vaginal orifice** lies in the midline of the vestibule. Its orifice is partial closed in the virgin by a fold of mucous membrane, the **hymen** (fig. 1049). Th is usually crescentic in shape, attached below to the posterior margin of the vagin orifice, and with a free edge extending anterosuperiorly. In some cases it diaphragmatic, i.e., attached all around, but perforated in the center. Tl remains of the hymen probably constitute the **caruncuIæ hymenales.** On eith side of the vaginal orifice, at its lower part, lie the racemose, muciparous, **vestibul glands** (glands of Bartholin), situated beneath the superficial perineal fasc and sphincter vaginæ. Their ducts run slightly upward and open, extern to the attachment of the hymen, within the labia minora. In relation to tl upper two-thirds of the vaginal orifice, placed between the urogenital diaphrag behind and the sphincter vaginæ in front, are the vascular **bulbs** of the vestibul rupture of which produces pudendal hematocele.

Fourchette and fossa navicularis.—The fourchette, as stated above, is tl posterior commissure of the labia minora. Normally the inner aspect of this in contact with the lower surface of the hymen. When the fourchette is pull down by the finger, a shallow depression is seen, the **fossa navicularis,** with tl fourchette for its posterior, and the hymen for its anterior, boundary.

Internal organs.—The examinations through the vaginal relations will l considered first, followed by uterus and appendages, ovary and ureter.

Examination per vaginam (Cf. figs. 1046, 1048).—The finger, introduced past the glute cleft, perineum, and fourchette, comes upon the elliptical orifice of the vagina, and notes hc far it is patulous or narrow; the presence or absence of any spasm from the adjacent muscle then, passing into the canal itself, the presence or absence of rugæ, a naturally moist or a d condition are observed. In the *anterior wall* the cord-like urethra can be rolled between tl finger and the symphysis; and further up than this, if a sound be passed, the posterior wall of tl bladder. The anterior wall of the vagina is about 6.7 cm. (2½ in.) long. The *posterior wa* 7.5 cm. (3 in.) long, forms the rectovaginal septum, and through it any feces present in tl bowel are easily felt. The cervix uteri is next felt for in the *roof* of the vagina, projecting dow ward and backward in a line from the umbilicus to the coccyx. Besides its direction, its siz shape, mobility, and consistence should be noted. The external orifice (os uteri) should form dimple or fissure in the center of the cervix. Of its two lips, the posterior is the thicker and mo fleshy feeling of the two. The vaginal fornix (anterior and posterior) is next explored. Th should be soft and elastic, giving an impression to the finger similar to that when it is intr duced into the angles of the mouth. Any resistance felt here may be due to scars, swellin connected with the uterus (displacements or myomata), effusions of blood or inflammato material, and, laterally, a displaced or enlarged ovary, or dilations of the Fallopian tube The posterior cul-de-sac is much deeper than the anterior, and, owing to the peritoneu descending upon the posterior wall of the vagina, when the finger is placed here it is onl separated from the peritoneal sac by the vaginal wall and pelvic fascia. In examination of th pelvic organs the bimanual method, by which one hand on the hypogastric region, pushes the down and steadies them as well, is always to be employed to complete an examination.

The uterus and appendages.—The normal non-gravid uterus is usuall anteflexed and anteverted so as to lie with its long axis approximately at righ angles to that of the vagina (fig. 1046). Its position varies considerably with th degree of distention of the bladder in front and of the rectum behind. Th distance from external orifice (os) to fundus, as estimated by the passage of sound is in the adult virgin uterus 5.5 cm. of which 3 cm. belong to the cervix an 2.5 cm. to the body. In the empty multiparous uterus the total length of th cavity is 6 cm., 2.5 cm. comprising the neck and 3.5 cm. the body.

Peritoneal relations (fig. 1046).—In front the peritoneum is reflected from the uterus t form the uterovesical pouch at the level of the isthmus. Behind it covers not only the uteru but the posterior fornix of the vagina, before turning off onto the front of the rectum. Laterall the peritoneum leaves the uterus and passes on to the lateral pelvic wall as a large twofol partition (fig. 1105), the broad ligament.

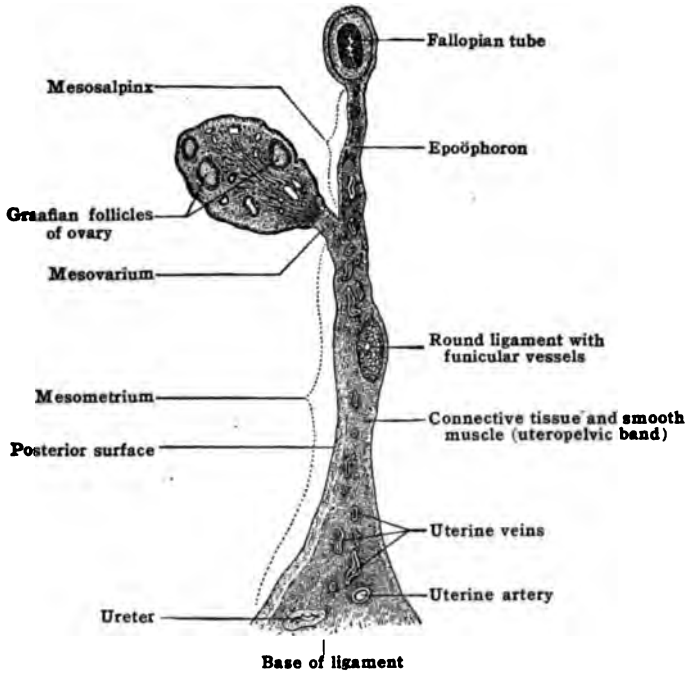
The **broad ligament,** bearing in its upper border the uterine tube, in front the round ligamen and behind the ovary, consists of (1) an upper thin part, the mesosalpinx lying above th attachment of the mesovarium, and containing the ovarian vessels and the epoöphoron, an below this (2) the thicker mesometrium, between the layers of which is a dense mass of fibrou tissue surrounding the uterine artery.

The anterior aspect of the cervix below the uterovesical pouch of peritoneum, is readily separable from the bladder with which it lies in contact, and the peritoneum may be raised off the uterus with ease in the lower part of its attachment both front and back. Over the upper part of the body and fundus, however, the peritoneal covering is firmly adherent, and cannot be dissected off.

Supports of the uterus.—The great mobility of the body of the uterus has been referred to above. The organ derives its support almost entirely from the attachments of the cervix and vaginal fornices. These rest on the pelvic floor, formed by the levator ani and perineal body which support them the more efficiently since the long axis of the vagina is at right angles to that of the uterus. Above the pelvic diaphragm the cervix is held up to the pelvic walls by strong specialized bands of fibromuscular tissue running in both anteroposterior and transverse directions. The chief of these, lying in the base of the broad ligaments is a fibrous sheath surrounding the uterine artery as it descends medially from the hypogastric. In the anteroposterior direction the uterovesical ligaments hold up the cervix to the pubes in front and the sacrouterine ligaments bind it to the anterior aspect of the sacrum behind. While firmly supporting the uterus these bands are elastic, and so do not fix it rigidly, but allow of the cervix being drawn downward by traction with vulsellum forceps.

For **lymphatics of uterus and vagina** see p. 777. For **blood-vessels**, see figs. 531, 571.

FIG. 1105.—SAGITTAL SECTION OF THE BROAD LIGAMENT.



The **ovary,** attached by its hilus to the mesovarium (figs. 1105, 1041, 1042), lies in a fossa at the back of the lateral wall of the pelvis just between the diverging external iliac and hypogastric vessels. To feel it the finger should be pushed well up in the side of the vagina toward the lateral wall of the pelvis. On the abdominal surface its position corresponds to the middle of a line drawn from the anterior superior iliac spine of that side to the opposite pubic tubercle (Rawlings).

The **lymphatics** of the ovary follow the ovarian veins (see p. 777). For **blood-vessels**, see figs. 525, 526, 571. Metastatic growths secondary to carcinoma or mixed tumors of the ovary will be found in the epigastrium, for the ovarian lymphatics drain into retroperitoneal lumbar lymph-nodes situated medial to the kidney.

The ureter.—The pelvic portion of this duct is of special importance in operations on the uterus and upper vagina.

It crosses the brim of the pelvis on either side at the bifurcation of the common iliac artery, or just in front of it, and descends on the side wall in front of the hypogastric artery, crossing the obliterated umbilical and obturator arteries. Curving forward and medially it passes under the base of the broad ligament (figs. 531, 1105), where the uterine artery crosses above it, and so gains the lateral angle of the bladder by passing across in relation to the lateral fornix of the vagina. In the base of the broad ligament the ureter lies about 2 cm. (⅘ in.) from the side of the cervix, and this relation must be borne in mind in excision of the uterus.

Pelvic floor.—The pelvic floor of the female corresponds in general to that of the male (see p. 1383). There are, however, important differences, due to the sexual organs. The *uro-*

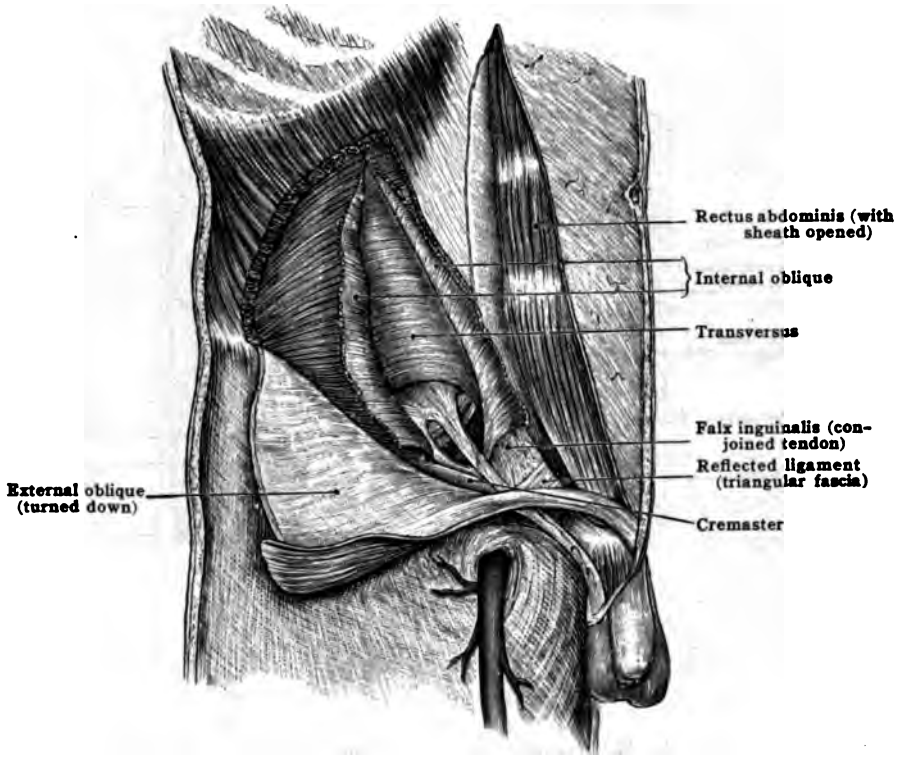
lata. On this inferior, stronger crus rests the cord (and so the weight of the testicle) or round ligament. **Shape**: triangular or elliptical, with the base downward and medially toward the pubic crest.

Intercrural fibers (intercolumnar fascia) (external spermatic fascia).—This, derived from the lower part of the aponeurosis of the external oblique, ties the two crura together, and, being continued over the cord, prevents there being any ring here, unless made with a scalpel. This is the rule in the body: when any structure passes through an opening in a fibrous or muscular layer, it carries with it a coating of tissue from that layer; e. g., the inferior cava passing through its foramen in the diaphragm, and the membranous urethra through the urogenital diaphragm.

Effect of position of the thigh on the ring.—As the lower crus is blended with Poupart's ligament, and as the fascia lata is connected with this, movements of the thigh will affect the ring much, making it tighter or looser. Thus extension and abduction of the thigh stretch the crura and close the ring. In flexion and adduction of the thigh the crura are relaxed; and this is the position in which reduction of a hernia is attempted. In flexion and abduction of the thigh, the ring is open; and this is the position in which a patient should sit, with thighs widely apart, to try on a truss, and cough or strain downward, as in rowing. If the hernia is now kept up, the truss is satisfactory.

FIG. 1107.—DISSECTION OF INGUINAL CANAL. (Wood.)



Helping to protect this most important spot, and preventing its being more than a potential ring, are not only the two crura and the intercrural fibers, but also a structure which has been called a third or posterior 'pillar,' namely, the **reflected inguinal ligament** (figs. 1106, 1107). This has its base above at the lower part of the linea alba, where it joins its fellow and the aponeurosis of the external oblique, and its apex downward and laterally, where, having passed behind the medial crus it blends with the lacunar (Gimbernat's) ligament. Again, the **falx inguinalis** (the conjoined tendon of the internal oblique and transversalis), curving medially and downward to be attached to the iliopectineal line and spine, is a most powerful protection, behind, to what is otherwise a weak spot and a potential ring.

Inguinal canal (fig. 1107).—This is not a canal in the usual sense, but a chink or flatsided passage in the thickness of the abdominal wall. The descriptions of the canal usually given apply rather to the diseased than to the healthy state. It was a canal once, and for a time only, i.e., in the later months of fetal life (p. 1387). It remains weak for a long time after, but only a vestige of it remains in the well-made adult.

Length.—In early life there is no canal; one ring lies directly behind the other, so as to facilitate the easy passage of the testis. In the adult it measures about 37 mm. (1½ in.) in length,

this lengthening being brought about by the growth and separation of the ala of the pel
This increased obliquity gives additional safety. On the other hand, a large hernia has not o
opened widely the canal and rings, but it has pulled them close together, and one behind
other thus not only rendering repair much more difficult, but also the path to the peritoneal
shorter and more direct. **Direction.**—From the abdominal to the subcutaneous ring, do
ward, forward, and medially.

Boundaries.—For convenience sake, certain limits (largely artificial) have been named
(1) *Floor.*—This is best marked near the outlet, where the cord rests on the grooved up
margin of the inguinal (Poupart's) and the lacunar (Gimbernat's) ligament. The meet
of the transversalis fascia with this ligament forms the floor. (2) *Roof.*—The apposition of
muscles and the arched border of the internal oblique and transversus. (3) *Anterior wall*
Skin, superficial fascia, external oblique for all the way. Internal oblique, i.e., that part aris
from Poupart's ligament, for the lateral third or so. To a slight extent, the transversus a
the cremaster. (4) *Posterior wall.*—For the whole extent, transversalis fascia, extraperiton
tissue, and peritoneum. For the medial two-thirds, conjoined tendon of internal oblique a
transversus, and the lateral edge of the reflected inguinal ligament, when developed.

The **transversalis fascia** is thicker and better marked at its attachments below; these ar
(*a*) laterally, to medial lip of iliac crest; (*b*) to the inguinal ligament between the anteri
superior spine and the femoral vessels, where it joins the fascia iliaca; (*c*) opposite the femo

vessel it also joins the fascia iliaca, and forms with it a funnel-shaped sheath; (*d*) medial to t
femoral vessels the fascia transversalis is attached to the terminal (iliopectineal) line, behi
the conjoined tendon, with which it blends.

The **falx inguinalis** (*conjoined tendon*) needs special reference figs. 1106–1108). It is formed
the lower fibers of the internal oblique and transversus (arciform fibers) arching downward ov
the cord to be inserted into the crest and spine and the terminal (iliopectineal) line. The fib
of the internal oblique become increasingly tendinous as they descend, and this, with the f
that below they give off the cremaster, may cause some difficulty in their identification wh
it is desired to unite them to the upper surface of Poupart's ligament in the operation of radi
cure.

The abdominal inguinal (internal abdominal) ring (figs. 1107, 1108).—
has already been said that the term 'ring' is here misapplied except in an artifici
sense, as when an opening is made by a scalpel; or in abnormal conditions when
hernial sac is present. The abdominal ring is not a ring in the least, but merely
funnel-shaped expansion of the transversalis fascia, which the cord carries on wi
it as it escapes from the abdomen.

Site.—Midway between the anterior superior iliac spine and pubic tubercle. Shap
oval, with the long diameter vertical. Boundaries: center of inguinal (Poupart's) ligame
about 12 mm. ($\frac{1}{2}$ in.) below. Medially, the inferior epigastric artery (fig. 1121); the positi

of this vessel, by its pulsation, is an important guide to the insertion of the highest sutures between the arciform fibers and the inguinal ligament. Owing to the artery lying to the medial side, the incision, in cutting to relieve the deep constriction of an inguinal hernia, should always be made directly upward, so as to avoid the above vessel. A large oblique hernia may so have altered the relations of the parts, including the artery, that it is difficult to decide whether the hernia is oblique or direct. The above incision will be safe, because, in either case, parallel to the vessel.

Forms of inguinal hernia.—There are two chief forms of inguinal hernia:—

A. **Lateral, or oblique.—Lateral,** because it appears (at the abdominal ring) lateral to the inferior epigastric artery. **Oblique,** because it traverses the whole of the inguinal canal, entering it at its inlet and leaving it at its outlet. This is the common form of inguinal hernia. In the oblique inguinal hernia, the hernial sac passes downward on the lateral and upper side of the spermatic cord, to which it is closely attached. If the fibers of the cremaster muscle are incised longitudinally the sac is exposed and can be easily isolated.

B. **Medial, or direct.—Medial,** because it appears medial to the inferior epigastric artery. **Direct,** because, instead of making its way down the whole oblique canal, it comes by a short cut, as it were, only into the lower part of the canal, and then emerges by the same opening as the other. This is the rarer form of inguinal hernia.

The sac in medial or direct hernia lies on the medial side of the spermatic cord to which it is not closely related. In the direct form considerable fat is always found in front of the peritoneum. The bladder is often closely related to the sac in the direct form and care should be taken not to injure it in freeing the sac. It may be necessary to divide the remains of the oblilerated hypogastric artery in order to free the sac.

A. **Oblique inguinal hernia.**—This form (which may be either congenital or acquired) possesses **coverings** as follows:—

(1) **At the abdominal ring,** or **inlet,** it obtains three:—(*a*) Peritoneum; (*b*) extraperitoneal fat; (*c*) infundibuliform fascia, or the vaginal process of transversalis fascia prolonged at this spot along the cord. (2) **In the canal** it obtains one. As it emerges beneath the lower border of the internal oblique it gets some fibers from the cremaster. (3) **At the subcutaneous ring,** or **outlet,** the hernia obtains three, viz.: (*a*) Intercrural fibers (intercolumnar fascia); (*b*) superficial fascia; and (*c*) skin.

B. **Direct inguinal hernia.**—This does not come through the abdominal ring, but, making its way through the posterior wall of the lower third of the canal, either through the medial or intermediate inguinal fossa. Its coverings, therefore, vary slightly with its mode of exit (*vide infra*).

Hitherto the two forms of inguinal hernia have been considered from the **superficial aspect,** that in which they are met with in practice. The inguinal region should also be studied as to the **posterior aspect** of its so-called rings and canal, as these have to bear the early stress of a commencing hernia. It is against this aspect that a piece of omentum or intestine is constantly and insiduously pressing and endeavoring to make its way out. On the posterior wall are certain peritoneal folds (cf. fig. 923) and depressions, marking off regions. Thus, there are three more or less prominent peritoneal *folds* (one median unpaired and two lateral paired) and three paired *fossæ*. The three folds are: (1) **median umbilical,** due to the *urachus*, a fibrous cord derived from the embryonic allantois, extending from the apex of the bladder to the umbilicus; (2) the **lateral umbilical fold,** enclosing the *obliterated hypogastric* artery, extending up to the umbilicus; and (3) the **epigastric fold,** enclosing the inferior epigastric vessels (figs. 923, 1108).

In relation to these folds are the following pouches or **fossæ**:—(*a*) A medial or **supravesical fossa,** between the median and lateral umbilical folds. Direct inguinal hernia may occur in the lateral part of this fossa, lateral to the margin of the rectus (fig. 1108). (*b*) Between the lateral umbilical and the epigastric fold is the **medial inguinal fossa,** an intermediate fossa, through which direct inguinal hernia may pass. (*c*) Most laterally is the **lateral inguinal fossa,** corresponding to the abdominal ring, through which oblique inguinal hernia passes.

The **coverings** of a direct hernia may now be considered, together with **the two-fold manner of exit** of this hernia. It only traverses the lower part of the canal, making its way through either the medial or the intermediate pouch. (i) The commonest form, coming through the medial (supravesical) pouch, either pushes its way through or stretches before it the falx inguinalis. Its *coverings* are:—(1) Peritoneum; (2) extraperitoneal fat; (3) transversalis fascia; (4) falx inguinalis (unless this is suddenly burst through); (5) (6) (7). At the subcutaneous ring the three coverings are the same as in the oblique variety. (ii) This rarer form of direct hernia comes through the intermediate pouch. As a rule, the falx inguinalis does not reach over this fossa. The coverings will be the same as in the last, with two exceptions—there is no falx inguinalis, and the cremasteric fascia, if well developed, will be present.

Varieties of inguinal hernia according to the condition of the vaginal process of peritoneum.—Inguinal herniæ have above been classified according to their relation to the deep epigastric artery. It remains to allude to the arrangement of these same herniæ according to the varying condition of the **processus vaginalis.** This pouch of peritoneum, which paves the way for the passage of the testis before this organ makes its start, eventually becomes the parietal layer

(p. 1387) of the tunica vaginalis below, in this fashion: During the first few weeks after bi the process becomes obliterated at two spots—one near the abdominal ring, and one j above the testis. The obliterative process, commencing first above and descending, and th ascending from below, the shrivelling continues until nothing is left save the tunica vagin below. The following are possible hernial results of an imperfect obliteration of the proces

(1) If the process does not close at all, a descending hernia is called congenital. This m make its way into the scrotum. The testis is now enveloped and concealed by the hernia

(2) If the process is closed only above, i. e., near the abdominal ring, two varieties may met with, *the infantile* and the *infantile encysted*. In the *infantile* owing to pressure above, weak septum g·adually yields and forms a sac behind the unobliterated lower part of the p cessus funiculovaginalis. Thus three layers of peritoneum may now be met with in an ope tion, the two of the incompletely obliterated tunica vaginalis, and the proper sac of the her In the encysted infantile variety the hernial pressure causes the septum to yield and form a projecting into, not behind, the incompletely obliterated tunica vaginalis. Here, theoretica two layers of peritoneum will be met with. Another variety of such an encysted hernia n be produced by rupture, not stretching, of the above-mentioned septum. The discussion these forms wh ch have been handed down by the older anatomists is of theoretical inter Surgically the classification is of little importance for the sac is removed usually without attempt at determining the number of layers of peritoneum in front of the contents.

(3) If the processus vaginalis be closed below and not above, a patent tubular proces peritoneum will lead down as far as the top of the testis. Any hernia into this process is ca a hernia into the funicular process. All these varieties save the congenital and hernia into funicular process are rare in practice. Other practical points are that all herniæ in children young adults are probably of congenital origin, and therefore, the weakness is often bilate though it may not be so palpably This applies to both sexes. Again in hernia of sud origin into the funicular process with narrow surroundings, strangulation may be very ac

Inguinal hernia in the female.—The inguinal canal in women is smaller and narrower t in men. Inguinal hernia is, therefore, less common in the female sex, and occurs in patients happen to be the subjects of an unobliterated processus vaginalis, which extends for a vary distance along the round ligament, and is called the *canal of Nuck*. Inguinal hernia in female is, therefore, always congenital. It is practically always of the oblique variety, travels along the round ligament toward the labium majus. Its coverings will be the same those of the oblique variety in the male, save that the cremaster, as a distinct muscle, is abs and any fibers of the internal oblique which may be present are but little developed.

In repairing a hernia, removal of the sac is one of the essentials. The sac should be remo high enough to obliterate any funnel-shaped process. In closing the canal, the Bassini operat in which the falx inguinalis (conjoined tendon) and the transveralis and internal oblique mus are sutured to the shelf of Pouparts ligament is still extensively employed. For operative tails, the surgical text-books should be consulted.

FEMORAL HERNIA

Parts concerned in femoral hernia.—These include (1) superficial fascia, inguinal (Poupart's) ligament, (3) lacunar (Gimbernat's) ligament, (4) fas lata, (5) fossa ovalis, (6) femoral sheath, (7) femoral canal, (8) femoral ring. (F 1110).

(1) **Skin and superficial fascia of groin.**—The latter consists of two laye (*a*) **Superficial layer of superficial fascia** (Camper's fascia).—Fatty, met with o the whole groin, and continuous with the superficial fascia of the rest of the bod (*b*) **Deep layer of superficial fascia** (Scarpa's fascia).—Thin and membrano only met with over the lower third of the abdominal wall and to the med side of the groin.

The latter is continuous through the scrotum with the deep layer of the superficial fas of the perineum (Colles' fascia). Just below the inguinal ligament it is joined to the fas lata. From these two facts it results that in rupture or giving way of the urethra the extra sated urine may come forward by way of the genitals (p. 1386) and from the continuity of fascia make its way on to the abdomen, but not down onto the thigh

Between the two layers of superficial fascia lie the superficial lymph nodes of the groin. superficial branches of the common femoral artery, cutaneous nerves, and some veins desce ing to the fossa ovalis to join the gerat saphenous vein.

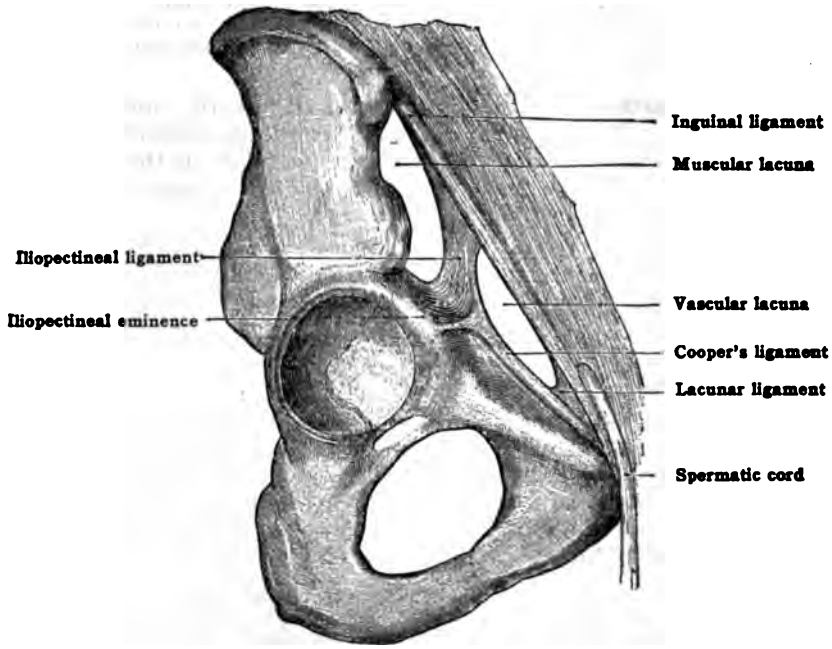
(2) **Inguinal (Poupart's) ligament** (fig. 1109).—This is also known as t crural arch, a misnomer, as 'crus' means leg. A description of its shape a attachments is given on p. 1371. Owing to the connection of the fascia lata its lower border, the fossa ovalis (saphenous opening), which is situated in t fascia lata, and has its upper cornu blending with the inguinal ligament, will affected by movements of the thigh, much as is the subcutaneous inguinal (ternal abdominal) ring, being tightened and stretched when the limb is extend and abducted, relaxed when it is adducted and flexed.

The parts beneath the ligament which block up the gap between it and t innominate bone are of the utmost importance in preventing the escape of

femoral hernia. The different structures are arranged in three compartments, (fig. 1109), named lateromedially:—(A) **lateral iliac** or **muscular**; (B) **central** or **vascular**; and (C) **medial** or **pectineal.** Of these, the first is the largest; the second or intermediate one lies slightly nearer to the inguinal ligament than the other two; while the medial compartment differs from the other two by not communicating with the pelvis, being closed above (*vide infra*).

(A) The **lateral** or **iliac compartment** is bounded in front by the inguinal ligament and the iliac fascia, which is here blending with it, behind by the ilium, laterally by this bone and the sartorius, and medially by the iliopectineal septum, which, descending from the blending of the iliac fascia and the inguinal ligament above, passes down to the iliopectineal eminence, and thence to the medial aspect of the front of the capsule of the hip-joint. This compartment transmits the iliopsoas muscle and femoral (anterior crural) and lateral cutaneous nerves. (B) The **vascular compartment** is bounded in front by the inguinal ligament and the transversalis fascia, which here blends with it, forming the so-called *deep crural arch*, and at the same time

FIG. 1109.—THE LACUNÆ BENEATH THE INGUINAL LIGAMENT. (Lockwood.)



descends on to the front of the femoral sheath. The posterior boundary, *Cooper's ligament*,[1] is formed by the meeting of the iliopectineal septum laterally and the pectineal fascia or sheath. Medially is the lacunar (Gimbernat's) ligament, and laterally the iliopectineal septum. This intermediate compartment transmits the external iliac vessels and the lumboinguinal nerve. This lies to the lateral side of the artery, the vein medially Between the vein and the base of the lacunar ligament is the femoral ring (*vide infra*). (C) The **medial or pectineal compartment** is bounded by the pectineal fascia, continuous with the pubic part of the fascia lata, and behind by the pubic ramus. It lodges the upper end of the pectineus muscle, so that the handle of a scalpel passed upward along the muscle would be prevented from passing into the pelvis by the lacunar ligament and the blending of the pectineal fascia with the upper border of the pubic ramus. The pectineal fascia is employed in some operations for the cure of femoral hernia.

(3) **Lacunar (Gimbernat's) ligament.**—This is merely the triangular medial attachment of Poupart's ligament. Its apex is attached to the pubic tubercle; of its three borders, the base is free toward the vein and the femoral canal. Its upper border is continuous with Poupart's ligament; its lower is attached to the terminal (iliopectineal) line (fig. 1109).

(4) **Fascia lata.**—Two portions are described over the upper part of the thigh:—(*a*) An **iliac,** lateral and stronger, attached to the inguinal ligament in its whole extent and lying over the sartorius, iliopsoas, and rectus. (*b*) A **pubic,** medial, weaker, and much less well defined, is attached above to the terminal line and the tubercle of the pubis. The upper cornu of the fossa ovalis is at the lacunar ligament, and at the lower cornu the two portions of the fascia blend.

Relation of fascia lata to the femoral vessels.—The iliac portion, being attached along Poupart's ligament, passes over these. The pubic portion, fastened down over the pectineus, which

slopes down on to a deeper plane than the adjacent muscles, passes behind the femoral ve to end on the capsule of the hip-joint.

(5) **Fossa ovalis (saphenous opening).**—This is not an opening, but an depression, situated at the spot where the two parts of the fascia lata diverg different levels. Though the fascia lata is wanting here, there is no real open as the deficiency is made up by the deep layer of superficial fascia, or cribrif fascia, which fills up the opening (fig. 420).

Though a weak spot, the fossa ovalis serves to transmit the saphenous to the femoral and the superficial to the deep lymphatics. The depression is present in order to allow saphenous vein to be protected from pressure in flexion of the thigh. It is located at the m and upper part of the thigh, with its center 3.7 cm. (1½ in.) below and lateral to the tub of the pubis. It is 2.5 cm. (1 in.) in height by 1.2 or 1.8 (½ or ¾ in.) in width. *Shape:* with its long axis downward and laterally. *Two extremities* or *cornua:* upper blending with lacunar ligament; lower, where the two parts of the fascia lata meet. *Two borders:* later falciform, also known as the *ligament of Hey*, or femoral ligament. Semilunar in shape, ar downward and laterally from the lacunar ligament to the inferior cornu. This lies ove femoral vessels, and is adherent to them; to it is fixed superficially the cribriform fascia *infra*). The medial border is much less prominent, owing to the recession of the pubic of the fascia lata which forms it.

(6) **Femoral sheath.**—This is a funnel-shaped sheath, carried out by femoral vessels under Poupart's ligament, and continuous above (in front) the transversalis fascia as it descends to the ligament, lining the inner surfac the abdominal wall, and (behind) with the iliac fascia, and below contin with the proper sheath of the femoral vessels.

It is not only funnel-shaped, but large and loose, for two reasons:—(*a*) That there be pl of room for the femoral vein and the slowly moving venous current in it to ascend without pression; (*b*) to allow all the movements of the thigh taking place—flexion and extensi without undue stretching of the vessels. By two connective-tissue septa the sheath is div into three compartments—the lateral for the artery, the intermediate for the vein, and medial one for the femoral canal (*vide infra*). Thus one septum lies between the artery vein, and another between the vein and the femoral canal.

(7) **Femoral canal.**—This occupies the medial division of the femoral she The fascia transversalis and fascia iliaca meet directly on the lateral side of femoral artery, but not so closely on the medial side of the femoral vein. He a space exists here, perhaps to prevent the thin-walled vein, with its slug current, from being pressed upon; but it is merely a slight gap, not a canal, un so made by a knife or by the dilating influence of a hernia.

Length: about 1.9 cm. (¾in.). *Limits:* below, fossa ovalis; above, femoral ring. *Bo aries.*—Laterally, a septum between it and the vein; medially, base of the lacunar ligam (above) and meeting of fasciæ iliaca and transversalis; behind, fascia iliaca; in front, fascia tr versalis. *Contents.*—Cellular tissue and fat, continuous with extra-peritoneal fatty layer a lymphatic node, which is inconstant. Lymphatic vessels pass from inguinal nodes to t in the pelvis through the femoral canal, which is therefore sometimes called the 'lymph canal' (fig. 1108).

(8) **Femoral ring.**—This is mainly an artificial product. It is the upper abdominal opening of the femoral canal (figs. 535, 1108, 1110). *Shape:* o with its long axis transverse. It is larger in women. *Boundaries:* media the lacunar ligament; laterally, the femoral vein; in front, the inguinal ligam and the thickening of the transversalis fascia attached to it (called 'the d crural arch'); behind, the pectineus and Cooper's ligament, a thickened fas bundle attached to the linea terminalis (fig. 1109). It is closed by the *sept crurale*, which is a mass of fatty connective tissue, continuous with the ex peritoneal fatty layer, perforated by lymphatics passing upward to the pe nodes (figs. 1108, 1110).

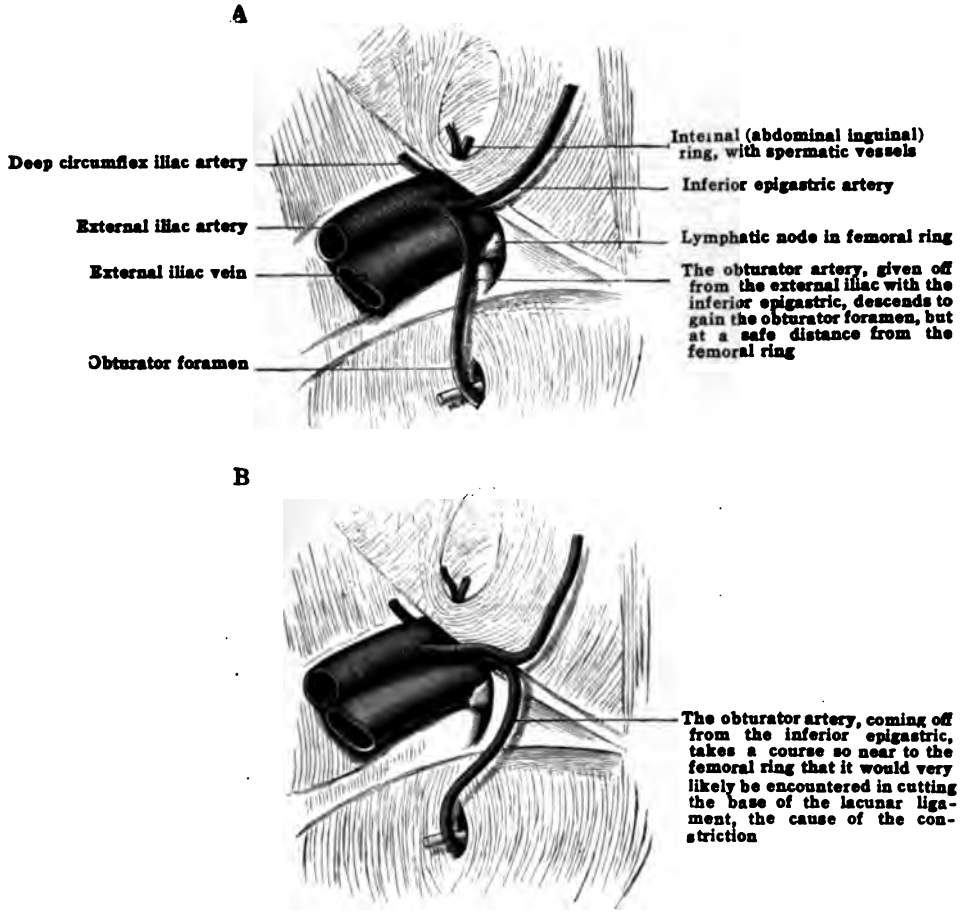
Position of vessels around the ring.—Laterally the femoral vein; above, epigastric vessels as they ascend from the external iliac vessels, pass close to upper and lateral aspect of the ring; immediately in front are the cord and s matic vessels always to be remembered in this hernia in the male; toward medial side there may be an unimportant anastomosis between the epigas artery above and the obturator below (fig. 1108).

If from dilation of the above anastomosis the obturator artery comes off abnormally f the inferior epigastric, it will descend, and usually does so, close to the junction of the exte iliac and common femoral vein, and thus to the lateral, and so the safe, side of the ring 1110, A). In a very few cases it curves more medially, close to the lacunar ligament,

thus to the medial side of the ring, and is then in great danger (fig. 1110, B) if the constricting femoral ring is incised. In two out of every five cases the obturator arises from the inferior epigastric. In about thirty-seven per cent. of the cases with such an origin the artery either crosses or courses along the side of the ring. (Cunningham.)

Course of femoral hernia.—At first this is downward in the femoral canal. A pouch of peritoneum having been gradually, after repeated straining, coughing, etc., pushed through the weak spot, the femoral ring, further weakened perhaps, together with all the parts in the femoral arch, by child-bearing, some extra effort will force intestine or omentum into this pouch and thus form a hernia. It has been recently claimed that some femoral herniæ are congenital; the peritoneal pouch which forms the sac being carried out with the limb-bud as it develops. When formed, femoral hernia passes at first downward in the femoral canal as far as the fossa ovalis, but, as a rule, does not go farther downward on the thigh, but mounts forward and upward, and somewhat laterally, even reaching the level of the inguinal ligament. The reasons for this change of position are:—(1) The narrowing of the femoral sheath, funnel-like, i. e.,

FIG. 1110.—FEMORAL RING AND IRREGULARITIES OF THE OBTURATOR ARTERY. (After Gray.)



A
Deep circumflex iliac artery
External iliac artery
External iliac vein
Obturator foramen
Internal (abdominal inguinal) ring, with spermatic vessels
Inferior epigastric artery
Lymphatic node in femoral ring
The obturator artery, given off from the external iliac with the inferior epigastric, descends to gain the obturator foramen, but at a safe distance from the femoral ring
B
The obturator artery, coming off from the inferior epigastric, takes a course so near to the femoral ring that it would very likely be encountered in cutting the base of the lacunar ligament, the cause of the constriction

wide above, but narrowed below; (2) the unyielding nature of the lower margin of the fossa ovalis; (3) the fact that this margin and the lateral border are united to the femoral sheath; (4) the constant flexion of the thigh; (5) the fact that vessels (chiefly veins) and lymphatics descend to the fossa ovalis, the veins to join the saphenous vein and the lymphatics to join the deeper group; these descending vessels serve to loop upward or suspend a femoral hernia, and thus prevent its further course downward. (For relations of femoral hernia, see fig. 1111.)

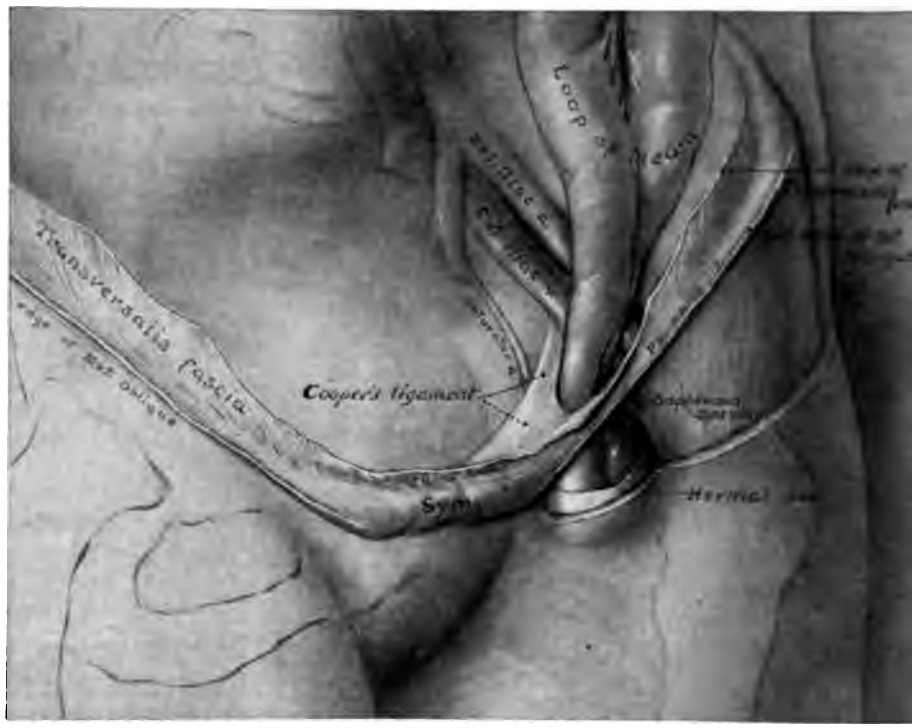
Coverings of a femoral hernia.—(A) **At the upper** or **femoral ring** it includes peritoneum, extraperitoneal fat, and septum femorale (crurale). (B) **In the canal,** a coating of the femoral sheath. (C) **At the external opening,** further coverings of cribriform fascia, skin, and superficial fascia are added.

Some of these coverings may be deficient by the hernia bursting through them, or they may be matted together. Sir A. Cooper thought this matting likely to occur with the layer of femoral sheath and septum crurale, to which he gave the name of *fascia propria.* The sac of a femoral hernia is usually covered by a relatively large amount of fat. At times there may be so much fat that the sac is found with difficulty.

The relations of an inguinal and a femoral hernia respectively to the pubic tubercle a importance in distinguishing between them clinically. If a finger is placed on the pubic tub a hernia that lies above and medial to it will be inguinal, one below and lateral to it wi femoral.

Radical cure of femoral hernia.—The close proximity of the femoral vein always i duces difficulty in the introduction of the deep sutures for closure of the crural ring. Any sure below this point is certain to be inefficient. The safest and simplest method is to for the pulsation of the femoral artery, and make allowance for the vein on its medial side. latter vessel is then protected by the finger-tip passed up the femoral canal, so that its do rests against the vein and its tip upon the linea terminalis. The sutures are then passe as to pick up the iliopectineal fascia and its thickened part, Cooper's ligament, below, and deep crural arch and Poupart's ligament above (fig. 1109). Thus, when tightened, they the anterior and posterior boundaries of the ring together. (Lockwood, Bassini.) There growing tendency to operate upon femoral hernia from above, that is through the ing canal. The hernial sac can thereby be completely removed, and the opening compl closed.

FIG. 1111.—RELATIONS OF FEMORAL HERNIA. (From Seelig and Tuholski; in Binnie's Regi Surgery.)



PARTS CONCERNED IN UMBILICAL HERNIA

A hernial protrusion at the umbilicus, or exomphalos, may occur at th distinct periods of life, according to the anatomy of the part. Any account umbilical hernia would be incomplete without an attempt to explain how t region, originally a most distinct opening, is gradually closed and changed i a knotty mass of scar, the strongest point in the abdominal wall.

During the first weeks of fetal life, in addition to the urachus, umbili arteries, and vein, some of the mesentery and a loop of the intestine pass thro the opening to occupy a portion of the body cavity (the umbilical celom) si ated in the umbilical cord, later on returning to the abdominal cavity (cf. p. 11 Occasionally this condition persists, owing to failure of development, and child is born with a large hernial swelling outside the abdomen, imperfec covered with skin and peritoneum. To this condition the term congen umbilical hernia should be applied.

Later on in fetal life it is the umbilical vessels alone which pass through t opening. At birth there is a distinct ring, which can be felt for some time a in the flaccid walls of the infant's belly. If this condition persists, a piec

intestine may find its way through, forming the condition which should be known as **infantile umbilical hernia.**

This condition is not uncommon. Why it is not more frequently met with is explained by the way in which this ring of infancy is closed and gradually converted into the dense mass of scar tissue so familiar in adult life. This is brought about—(1) by changes in the ring itself; (2) by changes in the vessels which pass through it.

(1) **Changes in the ring itself.**—The umbilical ring is surrounded by a sphincter-like arrangement of elastic fibers, best seen during the first few days of extrauterine life, on the posterior aspect of the belly wall. In older infants these fibers lose their elasticity, become more tendinous, and then shrink more and more. As they contract they divide, as by a ligature, the vessels passing through the ring, thus accounting for the fact that the cord, wherever divided, drops off at the same spot and without bleeding.

(2) **Changes in the vessels themselves.**—When blood ceases to traverse these, their lumen contains clots, their muscular tissue wastes, while the connective tissue of their outer coat hypertrophies and thickens. Thus, the umbilical vessels and the umbilical ring are, alike, converted into scar tissue, which blends together. This remains weak for some time, and may be distended by a hernia (infantile).

Finally, we have to consider the state of the umbilicus in adult life. The very dense, unyielding, fibrous knot shows two sets of fibers:—(1) Those decussating in the middle line; and (2) two sets of circular fibrous bundles which interlace at the lateral boundaries of the ring. The lower part of the ring is stronger than the upper. In other words, **umbilical hernia of adult life,** when it comes through the ring itself and not at the side, always comes through the upper part. In the lower three-fourths of the umbilicus the umbilical arteries and urachus are firmly closed by matting in a firm knot of scar tissue; in the upper there is only the umbilical vein and weaker scar. To the lower part run up the umbilical arteries and the urachus. Owing to the rapid growth of the abdominal wall and pelvis before puberty, and the fact that the urachus and the umbilical arteries, being of scar tissue, elongate with difficulty, the latter parts depress the umbilicus by reason of their intimate connection with its lower half.

Owing to the usual exit of an umbilical hernia of adult life being through the upper part of the ring, the constricting edge in strangulation should be sought below and divided downward. As pointed out by Mr. Wood, it is here that the dragging weight of the hernial contents and the weight of the dress tend to produce the chief results of strangulation. An incision here also gives better drainage if required.

Coverings of an umbilical hernia.—These, more or less matted together, are:—(1) Skin; (2) superficial fascia, which loses its fat over the hernia; (3) prolongation of scar tissue of the umbilicus gradually stretched out; (4) transversalis fascia; (5) extraperitoneal fatty tissue; (6) peritoneum. If the hernia come through above the umbilicus, or just to one side, the coverings will be much the same; but, instead of the layer from the umbilical scar, there will be one from the linea alba.

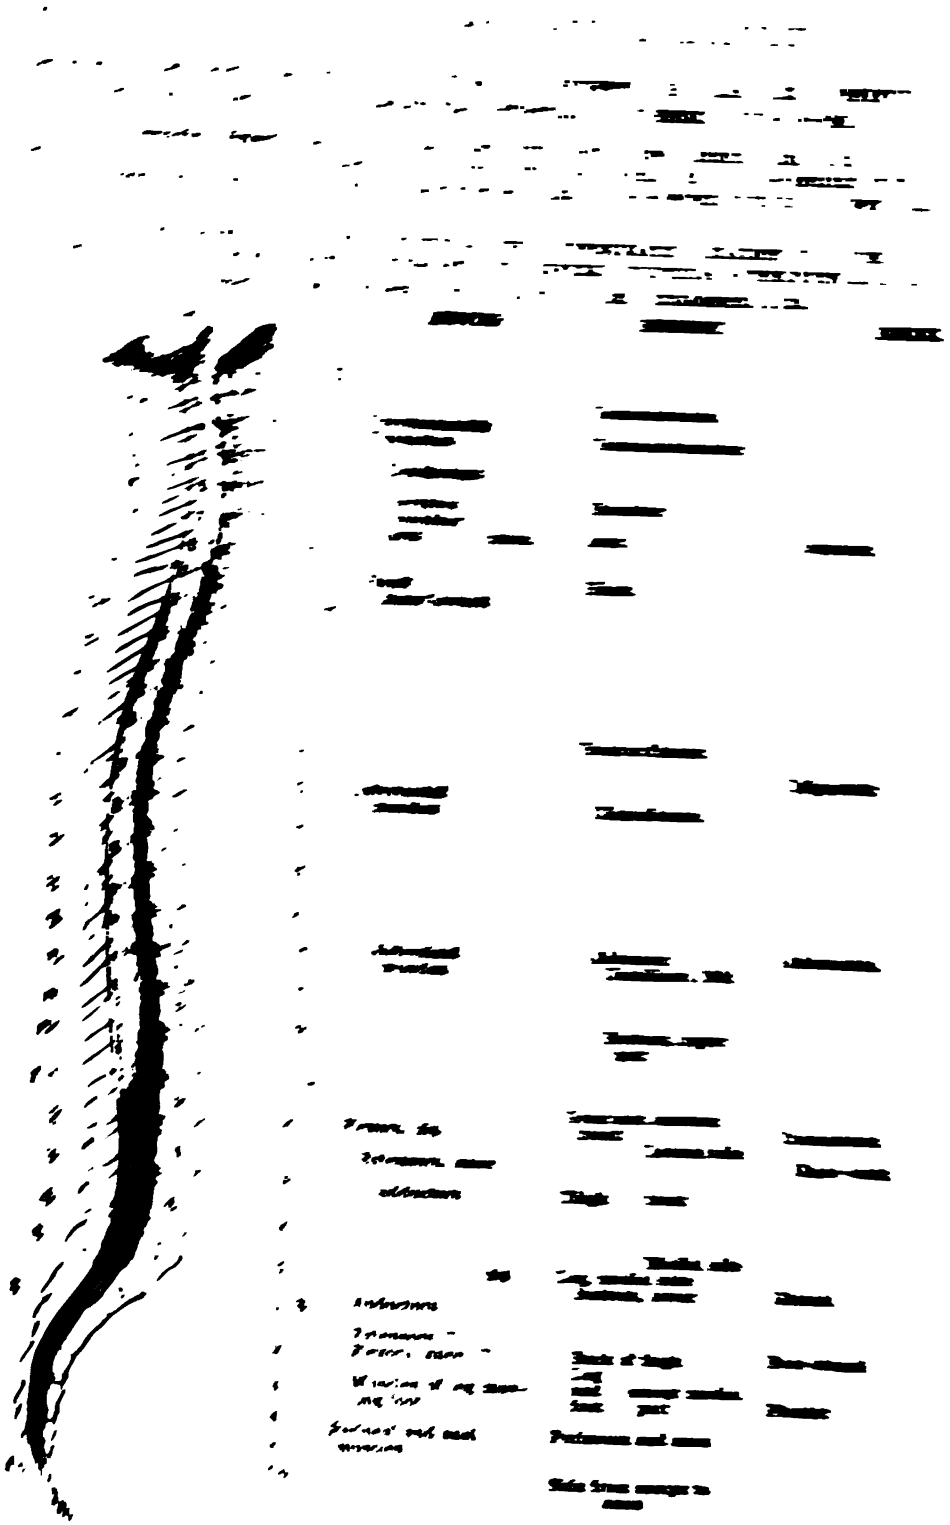
Strangulated umbilical hernia of adult life.—In this, the most fatal of the strangulated hernia ordinarily met with, the following are practical points in the surgical anatomy:—1. The coverings, including the sac, are always thin, at times so markedly so that the intraperitoneal contents are practically subcutaneous. 2. The sac is multilocular, and one or more of its chambers may lie very deep. 3. The contents are numerous, viz., omentum, often voluminous and adherent, transverse colon, and later in the history, small intestine. 4. The contents are often adherent to the sac and each other, thus explaining the irreducibility. 5. The long duration of the presence of the transverse colon with its stouter walls accounts for the period, often prolonged, in which warning evidence of incarceration precedes that of strangulation. 6. The communication with the peritoneal sac is direct, short, and during a prolonged operation, free. Infection is thus readily brought about.

THE BACK

The surface form and landmarks of the back will be considered first, followed by the relations of skeleton, muscles, viscera and nervous system.

Median furrow.—This is more or less marked according to the muscular development, lying between the trapezii and semispinales capitis, in the cervical region, and the sacrospinales lower down. The lower end of the furrow corresponds to the interval between the spines of the last lumbar and the first sacral vertebra. (Holden.)

Vertebral spines.—The tips of the spinous processes of the upper cervical region are scarcely to be made out even by deep pressure. That of the axis may be detected in a thin subject. Over the spines of the middle three cervical vertebra is normally a hollow, owing to these spines receding from the surface to allow of free extension of the neck. The seventh cervical is prominent, as its name



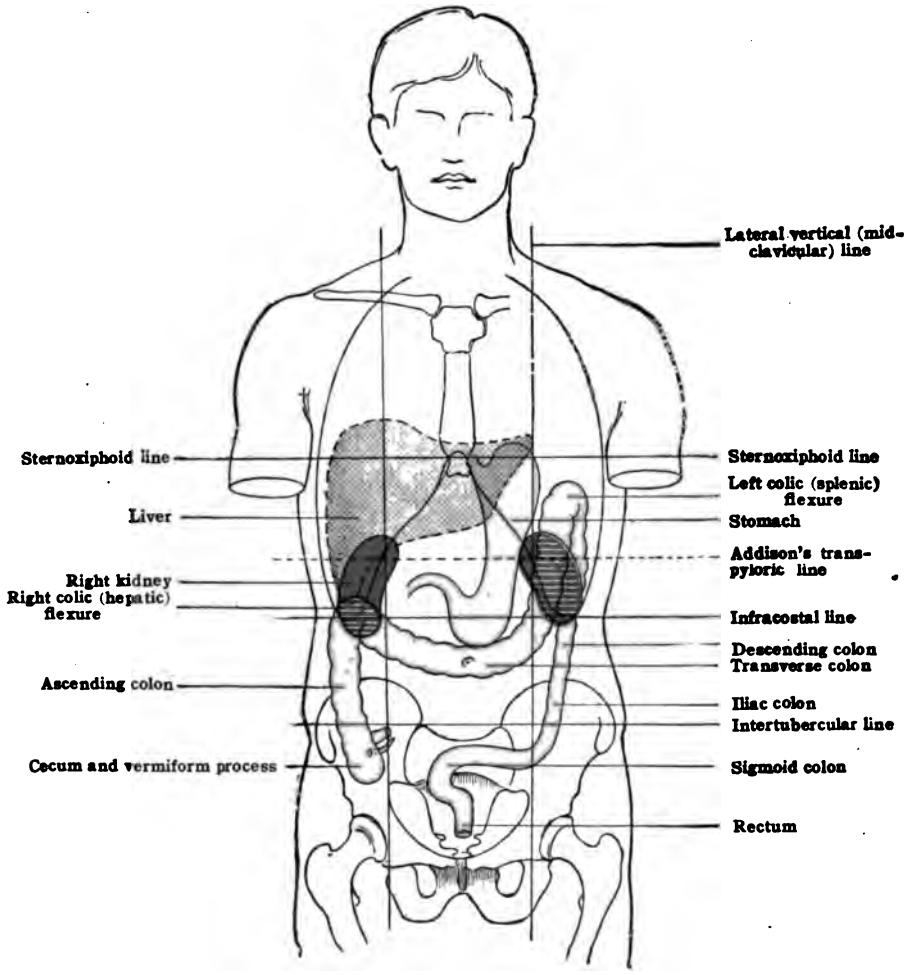
corresponds with the head of the te
and so on till we come to the eleven
their corresponding ribs. Holden.

In the lumbar spines, the most important are the second, which corresponds to the terma-
tion of the ribs and the fourth, which marks the highest part of the iliac crests and the
direction of the abdominal aorta. The lumbar spines project horizontally, and correspond

with the vertebral bodies. The third is a little above the umbilicus. The relations in Quincke's lumbar puncture are mentioned later.

The lower **ribs** may be felt lateral to the sacrospinalis but in counting them from below it must be remembered, as pointed out by Holl, that in quite a considerable percentage the last rib is so abnormally short that it does not reach as far as the lateral border of the sacrospinalis; or is so rudimentary as to resemble a transverse process (consequently the only safe method of counting ribs is from above). In these cases the lower end of the pleura may pass from the lower part of the twelfth thoracic vertebra, almost horizontally to the lower edge of the eleventh rib.

FIG. 1113.—RELATIONS OF THE ABDOMINAL VISCERA TO THE ANTERIOR BODY WALL. (Kidneys somewhat too widely separated.)



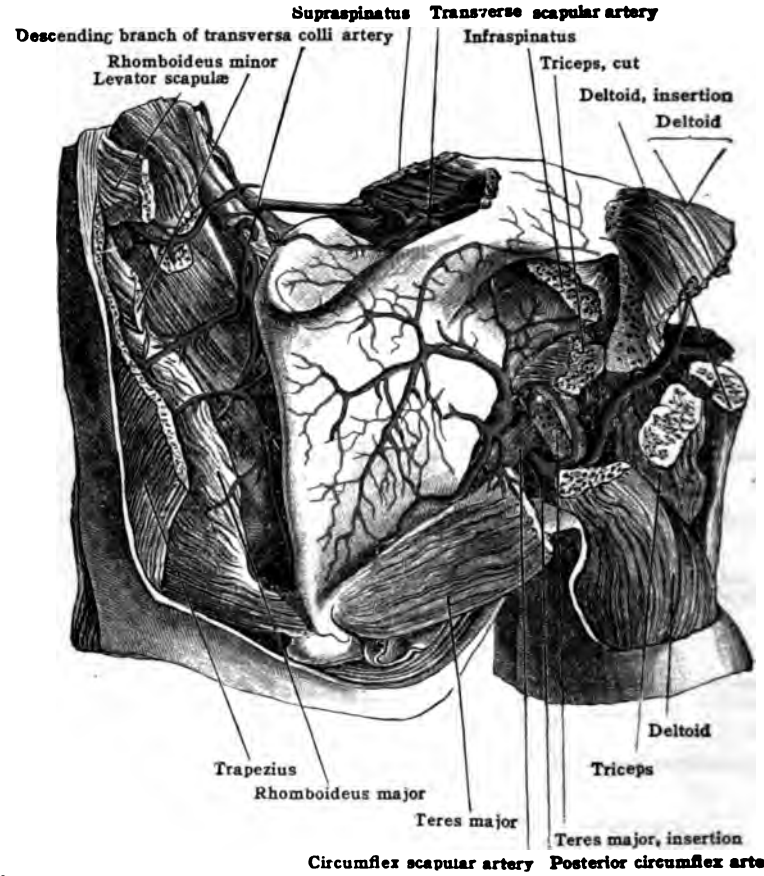
Muscles.—The student will remember the greater number and complexity and the numerous tendons of the muscles which run up on either side of the spinal column; the firmness and inextensibility of their sheaths; the large amount of cellular tissue between them; and the fact that toward the nape of the neck these muscles lie exposed instead of being protected in gutters, as is the case below: all these anatomical points explain the extreme painfulness and obstinacy of sprains here.

Trapezius.—To map out this muscle, the arm should be raised to a right angle with the trunk. The external occipital protuberance should be dotted in, and the superior nuchal line passing out from this; below, the twelfth thoracic spine should be marked; and laterally, the lateral third of the clavicle and the commencement of the scapular spine. Then a line should be drawn from the protuberance vertically downward to the twelfth thoracic spine; a second from about the middle of the superior nuchal line to the posterior and lateral third of the clavicle; and a third from the last thoracic spine upward and laterally to the root of the spine of the scapula.

Latissimus dorsi.—The arm being raised above a right angle, the spines of the sixth tho and the third sacral vertebra should be marked; then the outer lip of the crest of the ilium lower two or three ribs, the lower angle of the scapula, and the posterior fold of the axilla, finally the intertubercular (bicipital) groove should all be marked.

A vertical line from the sixth thoracic to the third sacral spine will give the spinal orig the muscle. Another from the third sacral spine to a point on the iliac crest, 2.5 cm. (1 in more lateral to the edge of the sacrospinalis, will give the origin of the muscle from the sh of the sacrospinalis and the ilium. A line from the sixth thoracic spine, almost transve at first, with increasing slight obliquity over the inferior angle of the scapula to the axilla intertubercular groove, will mark the upper border of the muscle. Another very oblique from the point of the iliac crest upward and laterally to the axilla will give the lower bo and the tapering triangular apex of the insertion. The muscle may be attached to the s of the scapula, or separated from it by a bursa.

FIG. 1114.—CHIEF ARTERIAL ANASTOMOSES ON THE SCAPULA.
(From a dissection in the Hunterian Museum.)



Triangle of Petit.—This small space lies above the crest of the ilium, at about its cen bounded posteriorly by the anterior edge of the latissimus and anteriorly by the posterior bor of the external oblique (fig. 418). Through this gap, when the muscles are weak, a lum abscess occasionally, and very rarely, a lumbar hernia, may appear.

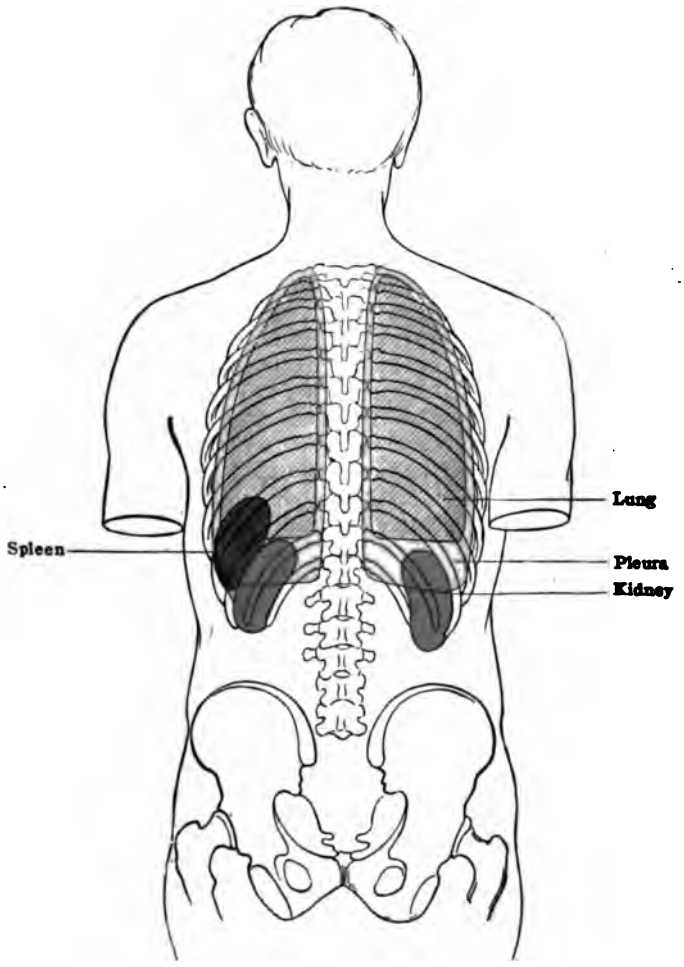
Origin of spinal nerves.—It is very important to remember the relations these to the vertebral spines, in determining the results of disease or injury of t cord and the parts thereby affected. The above relations may be given brie as follows:—

The origins of the eight cervical nerves correspond to the cord between the occiput and sixth cervical spine. The upper six thoracic come off between the above spine and that of fifth thoracic vertebra. The origins of the lower six thoracic nerves correspond to the inter between the fourth and the tenth thoracic spines. The five lumbar arise opposite the eleve and twelfth thoracic spines; and the origins of the five sacral correspond to the first lum spine. The diagram and table (fig. 1112), arranged by Dr. Gowers from anatomical a pathological data, show the relations of the origins of the *nerves* to their exits from the vertel canal, and the regions supplied by each. For further details on neural topography, see Sect on NERVOUS SYSTEM.

Scapula; its muscles and arterial anastomoses.—Amongst the landmarks in the back, the student should be careful to trace the angles and borders of the scapula as far as these are accessible. The upper border is the one most thickly covered. With the hands hanging down, the upper (medial) angle corresponds to the upper border of the second rib; the lower angle to the seventh intercostal space; and the root of the spine of the scapula to the interval between the third and fourth thoracic spines.

The axillary border of the scapula, covered by the latissimus dorsi and teres major, may best be palpated with the arm hanging to the side. The vertebral border is brought into prominence by placing the hand on the opposite shoulder. This border is held in apposition

FIG. 1115.—RELATIONS OF THE ABDOMINAL VISCERA TO THE POSTERIOR BODY WALL. (Kidneys somewhat too widely separated.)



with the thorax by the serratus anterior; consequently in paralysis of that muscle, supplied by the long thoracic nerve (5, 6, and 7 C.), it becomes unduly prominent, giving rise to 'winged scapula.' Figs. 505, 1089, 1114 show the chief arteries around the scapula. The anastomoses on the acromial process between the transverse scapular (suprascapular), thoracoacromial, and circumflex humeral arteries are not shown. The numerous **points of ossification**, primary and secondary, by which this bone is developed explain, in part, the frequency of cartilaginous and other growths here.

The anatomy of the loin behind, the **iliocostal region**, is of prime importance, owing to the numerous operations here. **The lateral border of the sacrospinalis and quadratus lumborum** may be indicated on the surface thus. (Stiles.) That of the sacrospinalis by drawing a line from a point on the iliac crest 8.2 cm. (3½ in.) (four fingers'-breadth) from the middle line upward and slightly laterally to the angles of the ribs. That of the quadratus passing upward and slightly medially lies a little lateral to that of the sacrospinalis at the crest, and a little medial to it at the twelfth rib. The ascending and the descending colon lie in the slightly depressed angle between the two muscles. The iliocostal region varies greatly in space according to the length of the lower ribs, shape of the chest, and development of the iliac crest. An

incision here—that for exploration of the kidney may be taken as the type—would be an obl one, about 10 cm. (4 in.) long, starting in the angle between the twelfth rib and the sacrospi muscle and passing forward and downward toward the anterior extremity of the iliac c In its upper part the incision should lie 1.2 cm. (½ in.) below the twelfth rib. The ant fibers of the latissimus dorsi are divided behind, the posterior ones of the external obliqu front. The yellowish-white lumbar fascia now comes into view, and is the first important l mark. It and the fibers of the internal oblique and transversus which arise from it are carefully divided. The last thoracic nerve and lowest intercostal artery may also req division. If the latter is cut close to the rib, the hemorrhage is troublesome. The transver fascia remains to be divided. To avoid the peritoneum, the deeper part of the incisions sh always be made from behind forward. If more room is required, as in large growths c exploration of the ureter, the incision must be prolonged beyond the iliac crest, the lumbo inguinal incision of Morris.

Viscera.—Several of these, which can be mapped in behind—viz., the kidn spleen, etc.—have been already mentioned (pp. 1375, 1380).

The commencement of the **trachea** and **esophagus** has been given in fron corresponding to the sixth cervical vertebra. If examined from behind, the of the corresponding spine would be a little lower down. The **trachea,** ab 12.5 cm. (5 in.) long, descending in the middle line, bifurcates opposite to interval between the third and fourth thoracic spines (or fourth and fifth bodi The **bronchi** enter the lungs at about the level of the fifth thoracic spine, the ri being the shorter, wider, and more horizontal. The **root of the lung** is oppo to the fourth, fifth, and sixth dorsal spines, midway between these and vertebral border of the scapula. The structures in it are the bronchus, pulmon artery, two pulmonary veins, bronchial vessels, lymphatics, and nerves. phrenic nerve is in front, the posterior pulmonary plexus behind. On the r side the superior vena cava is in front, the vena azygos (major) arching over root at the level of the fourth thoracic vertebra. On the *left* side the aorta arc over the root, and the thoracic aorta descends behind it. The **esophagus** 913), about 25 cm. (10 in.) in length, starting in the midline, curves twice to left, at first gradually at the root of the neck; from this point it tends to reg the middle line up to the fifth thoracic vertebra; thence finally turns again, a more markedly to the left, and passes through the diaphragm opposite to tenth, entering the stomach here or at the eleventh thoracic vertebra (ninth tenth thoracic spine). In the thorax this tube traverses first the superior, t the posterior, mediastinum. At three points, i.e., its commencement, where i crossed by the left bronchus, and at the cardiac orifice, it presents narrowi The relations of this tube to the pleura, pericardium, aorta, vagi, and thor duct are important in the ulceration of malignant disease and infected bod and in the passage of instruments.

The **aorta** reaches the left side of the vertebral column, with its arch just ab the fourth thoracic spine, and thence descends on the front of the column, wit slight tendency to the left, to bifurcate opposite the fourth lumbar spine.

The spinal cord.—This, about 45 cm. (18 in.) long, extends from the foran magnum to the junction between the first and second lumbar vertebræ. Up the third month of fetal life it reaches to the sacral end of the vertebral car later, owing to the more rapid growth of the bony wall, its lower limit is at bi opposite the third lumbar vertebra (cf. figs. 43–48). The dura mater is continu as a sheath over the subdural space, as low as the second sacral vertebra (f 748, 749). It is anchored above to the upper cervical vertebra and the foran magnum, and below, as the filum terminale, to the periosteum of the cocc The deficiency of the spinous processes and lamina of the fourth and fifth pie of the sacrum (hiatus sacralis) allows of infection, e.g., of a bed-sore reach the membranes, and so the cord. Solutions for local anesthesia may be injec through the hiatus into the spaces around the roots of the sacral nerves.

The parts of the spinal column most exposed to injury are the thoracolumbar and cervicothora partly because here more mobile parts are joined to those which are more fixed, and also fi the amount of leverage exerted on the thoracolumbar region; and, in the case of the up region, because this is affected by violence exerted on the head. *The chief provisions for p tection of the cord* are the number of bones and joints which allow of movement without ser weakening, the three curves and columns, cervical, thoracic, and lumbar, ensuring bend before breaking; the large amount of cancellous tissue and the number and structure of intervertebral disks all tending to damp vibrations; the large size of the dural sheath and way in which the cord, anchored and slung by the thirty-one pairs of nerves and the ligame denticulata, about twenty in number, occupies neutral ground in the center of the canal regards injury directly and indirectly applied (figs. 758, 759).

In **lumbar puncture** (Quincke) as a means of diagnosis or of relieving pressure advantage is taken of the fact mentioned above that the dural sheath extends below the cord. The relations are also important in injections for local (spinal) anesthesia.

A line drawn joining the highest points of the iliac crests crosses the fourth lumbar spine. The needle is inserted in the median line between the third and fourth or the fourth and fifth spines, and directed forward and slightly upward. The back must be flexed as fully as possible in order to widen the interspinous spaces. The needle is passed to a depth of about 5 cm. (2 in.) in an adult, or 1.8 cm. (¾ in.) in an infant. In the supine position the lowest part of the subarachnoid space is in the midthoracic region, and an anesthetic fluid, non-diffusible and of a higher specific gravity than the cerebrospinal fluid, will tend to gravitate there (Barker). The level of the anesthesia can be varied by raising the pelvis or the shoulders to different levels.

The following table, from Holden and Windle, with additions, will be found very useful in determining the relation of numerous viscera and other structures to the bodies of the vertebræ.

STRUCTURES AT LEVELS OF THE VERTEBRAL BODIES

Cervical

First. Level of hard palate.

Second. Level of free edge of upper teeth.

Second and third. Superior cervical ganglion of sympathetic.

Fourth. Hyoid bone. Upper aperture of larynx.

Fifth. Thyroid cartilage and rima glottidis. Between this and the last would be the bifurcation of the common carotid.

Sixth. Cricoid cartilage. Ending of pharynx and larynx. Consisting of the fused fifth and sixth ganglia, the middle cervical ganglion is usually opposite this vertebra. Here the omohyoid crosses the common carotid, and at this spot, the seat of election, the center of the incision for tying this vessel is placed. At this level the inferior thyroid passes behind the carotid trunk.

Seventh. Inferior cervical ganglion. Apex of lung. Arch of thoracic duct over apex of lung, outward and downward to termination.

Thoracic

First. Summit of arch of subclavian. (Godlee.) The height of this varies. Usually it is from 1.2 to 2.5 cm. (½ to 1 in.) above the clavicle. It is always in close relation with the cervical pleura.

Second. Level of episternal notch. This is usually opposite the disk between the second and third. Bifurcation of innominate. (Godlee.)

Third. Beginning of superior cava, at junction of first right costal cartilage with sternum. Highest part of aortic arch, about 2.5 cm. (1 in.) below notch.

Fourth. Bifurcation of trachea. Second piece of aortic arch, extending from upper border of second right costal cartilage, reaches spine. Arch of vena azygos. The superior mediastinum is bounded behind by the upper four thoracic vertebræ. Louis' angle, junction of manubrium and body of sternum. Thoracic aorta begins.

Fifth to ninth. Base of heart.

Sixth. Pulmonary and aortic valves, opposite third left costal cartilage at its sternal junction, in front. Commencement of aorta and pulmonary artery. End of superior cava, third right chondrosternal junction in front.

Seventh. Mitral orifice.

Eighth. Tricuspid orifice.

Ninth. Lower level of body of sternum and sternoxiphoid line (at lower border) Opening in diaphragm for inferior vena cava (lower border).

Tenth. Level of tip of xiphoid cartilage. Lower limit of lung posteriorly. Upper limit of liver comes to the surface posteriorly. Esophagus passes through diaphragm. Cardiac orifice of stomach (sometimes). Upper limit of spleen.

Eleventh. Lower border of spleen. Suprarenal gland. Cardia (sometimes).

Twelfth. Lowest part of pleura. Aorta passes through diaphragm (lower border). Celiac artery (lower border). Upper end of kidney.

Lumbar

First. Superior mesenteric arteries. Pancreas. Pelvis of kidney. Renal arteries. Transpyloric line (Addison.)

Second. Spinal cord ends at junction of first and second. Duodenojejunal flexure. Cisterna (receptaculum) chyli. Lower end of left kidney.

Third. Umbilicus, opposite disk between third and fourth. Lower end of right kidney.

Fourth. Bifurcation of aortic arch. Highest part of iliac crest.

Fifth. Commencement of superior vena cava.

Sacral

Second. End of sigmoid colon and beginning of first piece of rectum proper. Lower limit of dural sheath and subdural space.

Fifth. Reflection of rectovesical pouch of peritoneum 2.5 cm. (1 in.) above base of prostate.

Coccyx (tip). 2.5 cm. (1 in.) below this commencement of anal canal. Termination of filum terminale.

THE UPPER EXTREMITY

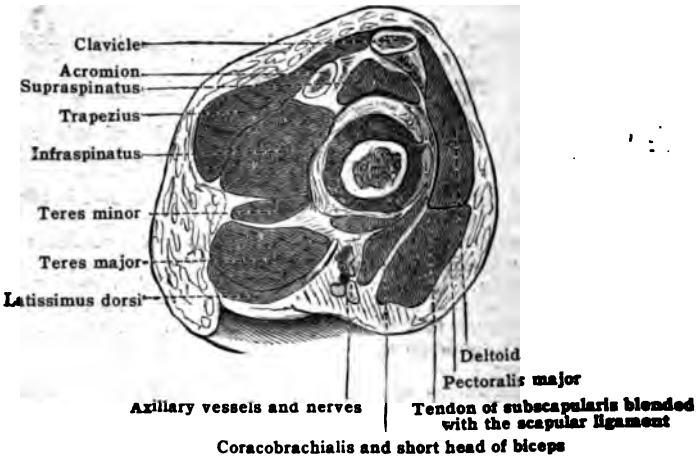
The surface form and landmarks of the upper extremity will first be consider followed by the various regions of the shoulder, arm, forearm and hand.

THE SHOULDER AND ARM

General surface form. Landmarks.—The following surface marks, of greatest importance in determining the nature of shoulder injuries, can be ma out here:—The **clavicle** in its whole extent, the **acromion process,** the gr **tuberosity,** and **upper part of the shaft of the humerus.** Much less distinct the position of the **coracoid process** in the infraclavicular fossa and the **head the humerus** through the axilla can be made out. The **anterior margin** of t **clavicle,** convex medially and concave laterally, can be **made out** in its wh extent, the bone, if traced laterally, being found not to be **horizontal,** but risi somewhat to its junction with the acromion. The **sterno- and acromioclavic lar joints** have been referred to on p. 1363.

The *frequency of fracture of the clavicle* is explained chiefly by its exposure to shocks of var kinds from the upper extremity, inseparable from the out-rigger-like action of the bone and early ossification. On the other hand, *the main safeguards* are the elasticity and curves of bone, the way in which it is embedded in muscles which will damp vibrations, and the buff

FIG. 1116.—TRANSVERSE SECTION THROUGH THE RIGHT SHOULDER-JOINT, SHOWING THE STRUCTURES IN CONTACT WITH IT. (Braune.)



bond articular disks at either extremity. The looseness and toughness of the overlying s explain the rarity of compound fracture here. The junction of the two curves is the weak spot and the usual site of fracture. The weight of the limb acting through the coracoclavicu ligaments and overcoming the trapezius is the chief factor in the downward displacement: t pectoralis minor and serratus anterior acting on the scapula draw the acromial fragment f ward. The tip of the *acromion*, when the arm hangs by the side with hand supinated, is the same line as the lateral condyle and the styloid process of the radius. On the medial s the head and medial condyle of the humerus and the styloid process of the ulna are in the sa line. Thus the *great tuberosity* looks laterally, the *head* medially, and the *lesser tuberosity* son what forward. Between the two tuberosities runs the intertubercular (bicipital) groove, whi with the arm in the above position, looks directly forward. In thin subjects its lower p can be defined. Its position can be marked with sufficient accuracy by a line running dow ward from the acromion in the long axis of the humerus. Besides the tendon and its synov sheath, the insertion of the latissimus dorsi, the humeral branch of the thoracoacromial arte and the anterior circumflex artery run in the groove. When the fingers are placed on the ac mion and the thumb in the axilla, the lower edge of the glenoid cavity can be felt; and if t humerus be rotated (the elbow-joint being flexed), the head of the humerus can be felt also.

The characteristic roundness of the shoulder is due to the great tuberosi lying under the deltoid (figs. 1117, 1118). In dislocation the loss of this roun ness is due to the absence of the head and tuberosity and consequent projecti of the acromion.

This normal projection of the deltoid renders it impossible to place a flat straight body contact with both the acromion and the lateral epicondyle at the same time (Hamilton's d

location test). Below the junction of the lateral and middle thirds of the clavicle, between the contiguous origins of the pectoralis major and deltoid, is the *infraclavicular fossa*, in which lie the cephalic vein, the deltoid branch of the thoracoacromial artery, and a lymphatic node which may be involved in obstinate tuberculosis of the cervical groups. On pressing deeply here, the coracoid process can be made out if the muscles are relaxed, and the axillary artery compressed against the second rib.

On raising the arm and abducting it, the different parts of the **deltoid** can often be made out —viz., fibers from the lower border of the spine of the scapula, the lateral edge of the acromion, and the lateral third or more of the front of the clavicle; the characteristic knitting of the surface

FIG. 1117.—ADULT SHOULDER-JOINT, AS SHOWN BY THE RÖNTGEN-RAYS. (Cf. fig. 216.)

owingl to the presence of fibrous septa continuous, alike, with the skin and the sheath of the muscle and the tendinous septa which separate the muscular bundles, will also be seen. The musce will be marked out by a base-line reaching along the above bony points, and two sides converging from its extremities to the apex, a point on the lateral surface of the humerus, about its center. In paralysis of the deltoid, the humerus being no longer braced up against the scapula, the finger-tips can be placed between it and the acromion.

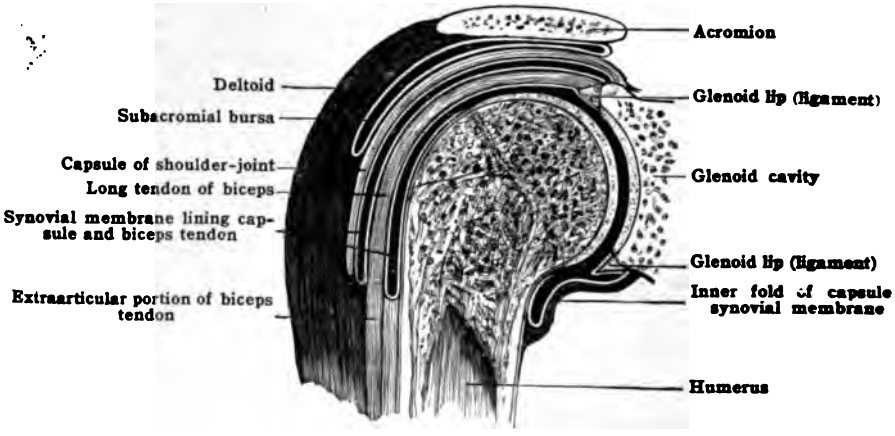
To map out the **pectoralis major,** a line should be drawn down the lateral aspect of the sternum as far as the sixth costal cartilage, and then two others marking the borders of the muscle—the upper corresponding to the medial border of the deltoid, the lower starting from the sixth cartilage, and the two converging to the folded tendon, which is inserted as a double layer into the lateral tubercular (bicipital) ridge. The **pectoralis minor** will be marked out by two lines, from the upper border of the third and the lower border of the fifth rib, just lateral to their cartilages, and meeting at the coracoid process. The lower line gives the level of the long thoracic artery; the upper, where it meets the line of the axillary artery, that of the thoracoacromial.

When the arm is abducted and the humerus rotated a little laterally, the prominence o well-developed **coracobrachialis** comes into view; a line drawn from the center of the clavi along the medial border of this muscle to its insertion into the humerus gives the line of t axillary artery.

Axillary fossa.—The boundaries of this space anterior, posterior, medial, thoracic, lateral or humeral, apex and base, with the structures forming them a the vessels and nerves in relation to them, must be remembered (see p. 405 a fig. 1116). The chief vessels are the axillary on the lateral wall, brought in prominence when the arm is abducted, as in removal of the mamma, and t subscapular on the posterior wall. The apex is felt, when the finger is push upward in an operation here, to be bounded by the clavicle in front, the first r behind, and the coracoid somewhat laterally. The base is concave, owing the coracoclavicular (costocoracoid) membrane as it descends to blend with t sheath of the pectoralis minor, giving also a process to the axillary fascia whi unites the anterior and posterior boundaries. This process also sends septa the skin.

An **axillary abscess,** always to be opened early to avoid subsequent interference with t movements of the shoulder, is reached by an incision on the medial wall, midway between t anterior and posterior boundaries, so as to avoid the long thoracic and subscapular vesse respectively, the back of the knife being directed toward the lateral wall. The only vessel this wall is the superior thoracic, which lies high up. Additional safety is given by the use Hilton's method. For **exploration** of the axilla the best incision is an angular one, the t

FIG. 1118.—DIAGRAMMATIC SECTION OF SHOULDER THROUGH THE INTERTUBERCULAR (BICI TAL) GROOVE. (Anderson.)



limbs being placed in a line with the anterior margin of the great pectoral, and in the line the axillary vessels. This runs from a point on the center of the clavicle (the limb being at right angle to the trunk) to the medial margin of the coracobrachialis. If this be obliterat by swelling, the above line should be prolonged to the middle of the bend of the elbow, whi will give the guide to the brachial also. **Collateral circulation.** If the first part of the arte be tied, the channels are the same as in ligature of the third part of the subclavian (*q.v.*). ligature of the third part of the axillary, if the ligature be *above* the circumflex arteries, the chi vessels concerned are the transverse scapular (suprascapular) and thoracoacromial above a the posterior circumflex below. If the ligature be *below* the circumflex, the anastomoses will those concerned in ligature of the brachial above the profunda (p. 1415). The lymphat nodes in the axilla have been mentioned at p. 753 (fig. 605).

The depression of the **axillary fossa** is best marked when the arm is raised from the s to an angle of about 45°, and when the muscles bounding it in front and behind are contracte In proportion as the arm is raised, the hollow becomes less, the head of the humerus now pr jecting into it. When the folds are relaxed by bringing the arm to the side, the fingers can pushed into the space so as to examine it.

The axillary (circumflex) nerve and posterior circumflex vessels wind around the humer under the deltoid; a line drawn at a right angle to the humerus and a little above the cent of this muscle marks their position on the surface.

To trace the **synovial membrane of the shoulder-joint is a comparative** simple matter (fig. 1118). Covering both aspects of the free edge of the glenoi ligament, it lines the inner aspect of the capsule, whereby it reaches the articul margin of the head of the humerus; there is a distinct reflection, below, from t capsule on to the humeral neck before the rim of the cartilage is reached.

An extensive protrusion of synovial membrane takes place in the form of a synovial bursa, at the medial and anterior part of the capsule, near the root of the coracoid process under the tendon of the subscapularis. Another protrusion takes place between the two tuberosities along the intertubercular groove, as low as the insertion of the pectoralis major. A third synovial protrusion may be seen, but not frequently, at the lateral or posterior aspect, in the form of a bursa, under the infraspinatus tendon. Thus the continuity of the capsule is interrupted by **two** and **sometimes three synovial protrusions.**

A large bursa is found beneath the deltoid which is continuous above with the subacromial bursa (fig. 1118). The subdeltoid bursa does not communicate with the shoulder-joint. It frequently becomes inflamed. When inflamed it may seriously interfere with movement of the shoulder joint. It may even become calcified, giving an *X*-ray shadow lateral to the head of the humerus.

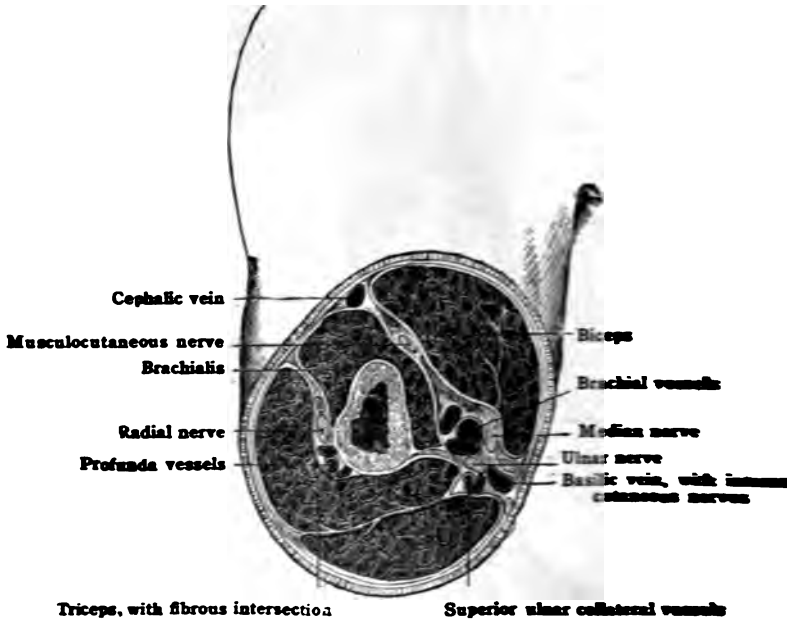
Shoulder-joint.—The frequency of **dislocations** here calls attention to the points contributing to make the joint alike insecure and safe. **Strength** is given by (1) the intimate blending of the short scapular muscles, especially the subscapularis with the capsule; (2) the coracoacromial vault; (3) atmospheric pressure; (4) the long tendon of the biceps; (5) the elasticity of the clavicle; (6) the mobility of the scapula. The **weakness of the joint** is readily explained by its free mobility, the want of correspondence between the articular surfaces, its exposure to injury, and the length of the humeral lever.

The rent in the capsule is usually anterior and below, and to this spot the head of the humerus must be made to return. While dislocations are usually primarily subglenoid, owing to the above part of the capsule being the thinnest and least protected, they take usually a secondarily forward direction, as the triceps prevents the head passing backward. The coracohumeral ligament usually remains intact and is used in manipulations to reduce the disloca-

triceps and brachialis (anterior), and the lateral one giving origin to the [illegible] nator longus) and extensor carpi radialis longus as well. The medial extends up to of the coracobrachialis, the lateral to that of the deltoid. The lateral septum s the anterior part of the profunda vessels and the radial (musculospiral nerve. The superior and posterior branch of the inferior ulnar collateral (anastomotica magna the ulnar nerve.

FIG. 1120.—CROSS-SECTION THROUGH THE MIDDLE OF THE RIGHT ARM



The **biceps** has a twofold attachment above and below. The former is of much in steadying the various movements, especially the upward one, and in harmonizing taneous flexion and extension of the shoulder- and elbow-joints. (Cleland. T fibrosus curving downward and medially with its semilunar edge upward, across th

A line drawn along the medial edge of the biceps from the insertion of the teres major to the middle of the bend of the elbow corresponds to the **brachial artery.** In the upper two-thirds, this artery can be compressed against the bone by pressure laterally; in its lower third the humerus is behind it, and pressure should be made backward. The presence of the median nerve will interfere with any prolonged digital pressure applied in the middle of the arm.

In **ligature of the artery** here the line extends from the midaxillary region above, prolonged to the center of the front of the elbow. The only structures seen should be the medial edge of the biceps, the basilic vein, and the median nerve. The profunda comes off 2.5 cm. (1 in.) below the teres major, having the same relation to the heads of the triceps; thus, it first lies on the long head, behind the axillary and brachial arteries, then between the long and medial heads, and next, in the groove, between the medial and lateral heads, and courses with the radial (musculospiral) nerve (fig. 1120); the nutrient artery arises opposite the middle of the humerus; in many cases it arises, on the back of the arm, from the profunda; the superior ulnar collateral (inferior profunda) below the middle, and courses with the ulnar nerve through the intermuscular septum to the back of the medial condyle. The inferior ulnar collateral (anastomotica magna) is given off from 2.5 to 5 cm. (1 to 2 in.) above the bend of the elbow. Fig. 1126 will show the **collateral circulation** after ligature of the brachial, according as the vessel is tied above or below the superior profunda, or below the superior ulnar collateral.

The **center of the arm** is a landmark for many anatomical structures. On the lateral side is the insertion of the deltoid; on the medial, that of the coracobrachialis. The basilic vein and the medial brachial cutaneous nerve (nerve of Wrisberg) here perforate the deep fascia, going in reverse directions. The superior ulnar collateral is here given off from the brachial and joins the ulnar nerve; the median nerve also crosses the artery, and the ulnar nerve leaves the medial side of the vessel to pass to the medial aspect of the limb.

FIG. 1121.—CROSS-SECTION THROUGH THE ELBOW. (× 1/2). (After Braune.)

The **brachialis** can be mapped out by two pointed processes which surround the insertion of the deltoid, pass downward into lines corresponding to the two intermuscular septa, and then converge over the front of the elbow to their insertion into the coronoid process.

The **median nerve** (lateral head, 5th, 6th, 7th C.; medial head, 8th C. and 1st T.) can be traced by a line drawn from the lateral side of the third part of the axillary and first part of the brachial artery, across this latter vessel about its center, and then along its medial border to the forearm, where it passes between the two heads of the pronator teres.

The **ulnar nerve** (8th C. and 1st T.) lies to the medial side of the above arteries as far as the middle of the arm, where it leaves the brachial to course more medially and perforate the medial intermuscular septum together with the superior and posterior branch of the inferior ulnar collateral and so get to the back of the medial condyle. A line drawn from the medial border of the coracobrachialis, where, in the upper part of its course, the nerve is in close relation with the medial side of the axillary and brachial arteries, to the back of the medial condyle, will indicate its course. Low down, the nerve is in the medial head of the triceps, and may be injured in operations here.

The **radial (musculospiral) nerve** (5th, 6th, 7th, and 8th C.) can be traced by a line beginning behind the third part of the axillary artery, then carried vertically down behind the uppermost part of the brachial, and then, just below the posterior border of the axilla, curving backward behind the humerus and slightly downward just below the insertion of the deltoid. Thus, passing from laterally and from before backward in its groove, accompanied by the profunda vessels, first the trunk, and then the smaller anterior division, it again comes to the front by perforating the lateral intermuscular septum at a point about opposite to the junction of the middle and lower thirds of the arm, and passes down in front of the lateral supracondyloid ridge, lying here between the brachioradialis and brachialis anterior, to the level of the lateral condyle, in front of which it divides into the superficial (radial) and deep (posterior interosseous) radials. The former of these accompanies the radial artery to the front of the forearm, the latter travels backward to the back of the forearm. A line from the lateral condyle to the insertion of the deltoid indicates the lateral intermuscular septum.

In addition to injuries caused by fracture, the nerve may be injured in crutch pressure, the sleep of intoxication, use of an Esmarch's bandage, or the careless reduction of a dislocated shoulder with the foot in the axilla. To expose the nerve the incision begins below, over the

lateral intermuscular septum, where it lies between the brachioradialis and brachialis anterior. Hence the incision is prolonged freely upward and backward toward the posterior border of the deltoid.

On the back of the arm is the **triceps muscle** (figs. 1119, 1120), with its three heads and tendon of insertion, all brought into relief in a muscular subject when the forearm is strongly extended. Of the three heads, the medial is the least distinct, arising below the groove (musculospiral) for the radial (musculospiral) nerve, reaching to each intermuscular septum, and tapering away above as high

FIG. 1122.—THE ELBOW-JOINT, AS SHOWN BY THE RÖNTGEN-RAYS. (Epiphyses visible

as the teres major. Most of the fibers of this head lie deeply. The lateral head, arising above the groove as high as the great tuberosity, appears in strong relief just below the deltoid; while the middle or long head, arising from the scapula just below the glenoid cavity, appears between the teres muscles. The tendon of insertion, passing into the upper and back part of the olecranon over a deep bursa, is shown by a somewhat depressed area. On the lateral side, an important expansion to the fascia over the anconeus is given off.

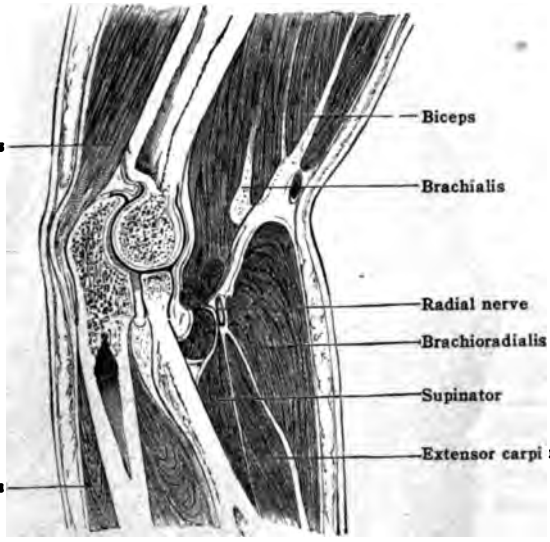
In the ossification of the humerus the epiphyses are of first importance. The upper, consisting of those for the head and two tuberosities, which form one about the seventh year, blends with the shaft between the twentieth and twenty-fifth years. Separation usually takes place at an earlier date, this being explained by the fact that the cone-like arrangement by which the diaphysis fits into the cap of the epiphysis becomes more marked toward the date of union and thus tends to prevent displacement. Thomson. The lower epiphysis (figs. 223, 1122). The condition of this varies with the degree of coalescence of its four centers. The first and chief, that for the capitulum, second or third year, unites with those for the trochlea and lateral epicondyle soon after puberty, and forms an epiphysis which joins with the shaft at about sixteen. The epiphysis for the medial epicondyle appears at the fifth year and unites with the

shaft at the eighteenth. Injury to this epiphysis may damage the ulnar nerve and open the elbow-joint. Thus, at and after puberty, there are two chief epiphyses to remember here:—(*a*) the larger, consisting of capitular, trochlear, and lateral epicondyle centers. This is almost entirely intra-articular; (*b*) the smaller, that for the medial epicondyle; the extent to which this is intra-articular varies. The structures that would be divided in **an amputation at the center of the arm** are shown in fig. 1120. The chief points needing attention are:—(1) To leave as much of the lever of the humerus as possible; (2) clean section of the large nerves, the radial (musculospiral) in its groove being especially liable to be frayed by the saw; (3) the difference between the amount of retraction of the free biceps in front, and the triceps behind, fixed to the bone and septa.

THE ELBOW

The **bony points,** epicondyles, olecranon, and head of radius, and their relation to one another, should be carefully studied. The *medial epicondyle* is the more prominent of the two, is directed backward as well as medially, and lies a

FIG. 1123.—LONGITUDINAL SECTION OF THE ELBOW-JOINT. (× ½). (Braune.)

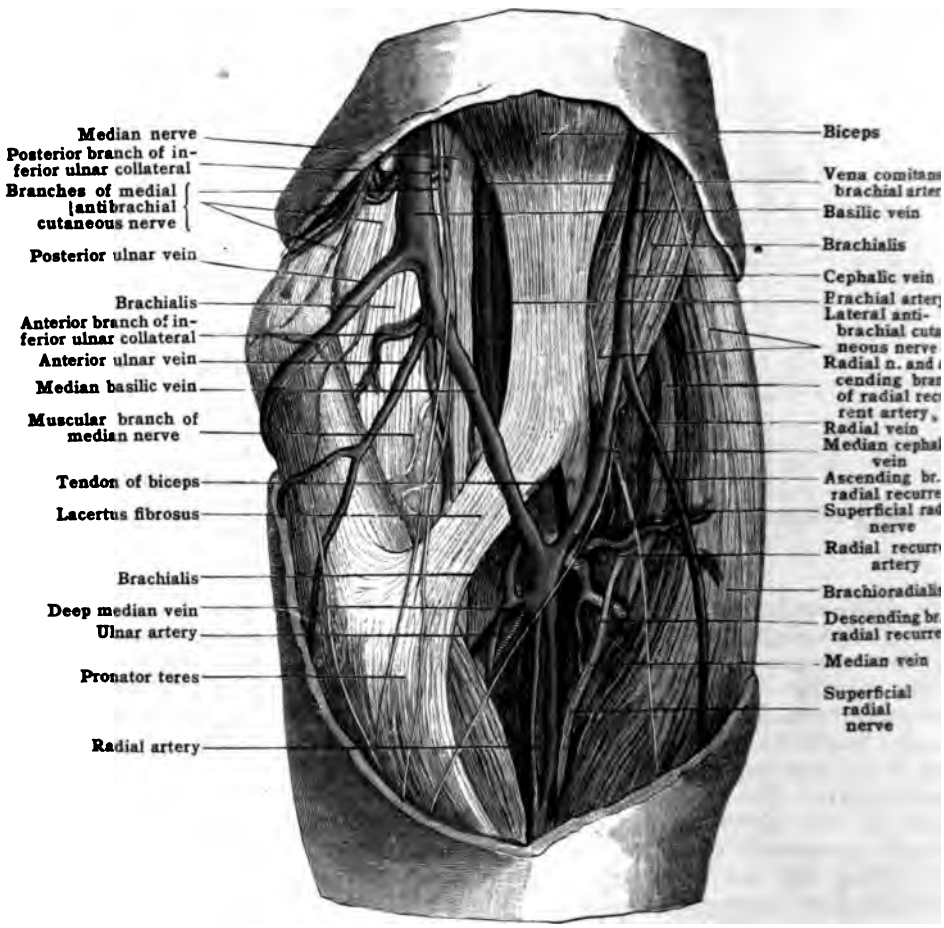


little above its fellow. Above it can be traced upward the supracondyloid ridge and corresponding intermuscular septum. The *lateral epicondyle* is more rounded, and thus less prominent; below, and a little behind it, the *head of the radius* can be felt moving under the capitulum when the forearm is supinated and flexed. A depression marks this spot and corresponds to the interval between the anconeus and brachioradialis and extensor carpi radialis longus; at the back, the upper part of the *olecranon* is covered by the triceps. The lower part is subcutaneous, and separated from the skin by a bursa. If the thumb and second finger be placed on the epicondyles and the index on the tip of the olecranon, and the forearm completely extended, the tip of the olecranon rises so as to be on the line joining the two epicondyles. In flexion at a right angle, the olecranon is below the line of the epicondyles, and in complete flexion quite in front of them. Between the medial epicondyle and olecranon is a pit, in which lie the ulnar nerve and the anastomosis between the inferior ulnar collateral and the posterior ulnar recurrent arteries. The coronoid process is so well covered by muscles, vessels, and nerves that its position cannot be distinctly made out.

The synovial membrane of the elbow-joint communicates with that of the superior radio-ulnar. Hence the facility with which tuberculous disease may be set up after neglected falls on the hand, in early life. At this time the weakness of the annular (orbicular) ligament leads to its being easily injured. Swelling, due to effusion into the joint, appears on either side of the triceps tendon, and soon obliterates the depression below the lateral epicondyle. The simplest incision of an infected elbow-joint is a vertical one, on the lateral side of the olecranon. A superficial swelling over the tip of the olecranon is due to effusion into the subcutaneous bursa (miner's elbow). A deeper, less easily defined swelling in the same region is due to inflammation of the bursa between the olecranon and the triceps. A swelling on the medial side of the elbow-joint, if painful and accompanied by inflammation of the skin, may be due to mischief in the **epitrochlear lymphatic node** situated just above the medial epicondyle, and receiving lymphatics from the medial border of the forearm and the two medial fingers.

The hollow in front of the elbow (figs. 1124, 1125, 1127).—The delicacy of the skin here n always be borne in mind in the application of splints. Owing to the insidious rapidity v which pressure may set up ischemic paralysis, anterior angular splints are always to be u with caution. The **M-like arrangement of the superficial veins as usually described** is by means constant (figs. 567, 1124). The median basilic is the vein usually chosen for venesect and for intravenous injections, owing to its larger size and its being firmly supported by subjacent bicipital fascia (lacertus fibrosus) which separates it from the brachial artery; but median cephalic is the safer. The median basilic is crossed by branches of the medial a brachial (internal) cutaneous nerve, while those of the musculocutaneous lie under the me cephalic. In the semiflexed position, the fold of the elbow is seen, a little above the l of the joint. This forms the base of the *triangular cubital fossa* below the elbow, the lat side corresponding to the brachioradialis, the medial to the pronator teres, and the apex to meeting of these muscles. The tendon of the biceps can be easily made out in the center of fossa, giving off the lacertus fibrosus above from its medial side to fasten down the flexors of

FIG. 1124.—THE BEND OF THE ELBOW WITH THE SUPERFICIAL VEINS.
(From a dissection by Dr. ALDER SMITH in the Museum of St. Bartholomew's Hospital.



forearm. Under the tendon on its medial side lie the **brachial artery and the median nerv** little medial to it, for a short distance. The radial nerve (**musculospiral**) **lies outside the fos** between the brachioradialis and the brachialis (anterior), and **gives off its two terminal branc** in front of the lateral epicondyle. The brachial usually bifurcates **opposite to the neck of** radius.

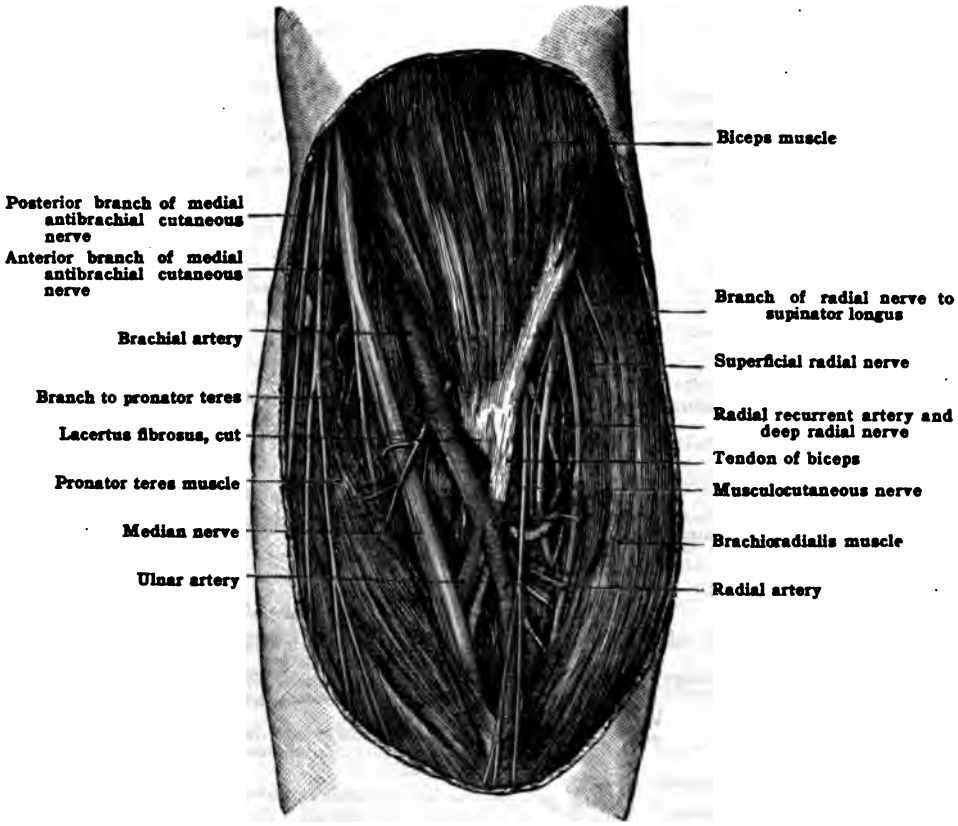
The **arterial anastomoses about the elbow-joint** (fig. 1126) are as follows: **The radial recurr** runs up under cover of the brachioradialis to anastomose with **the anterior branch of the p** funda **on the front of the lateral condyle.** The posterior interosseous **recurrent ascenda, betw** the supinator and the anconeus, to anastomose **on the back of the lateral condyle with the jp** terior branch of the profunda. It further joins, by a large **anastomotic arch across the bac** the joint, with the inferior ulnar collateral (anastomotica **magna**) **and posterior ulnar recurre** The anterior ulnar recurrent passes upward on the brachialis **to join the anterior part of** inferior ulnar collateral under the pronator teres, on the **front of the medial epicondyle.** posterior ulnar recurrent makes for the interval between **the back of the medial epicond** and the olecranon, to join with the superior and the **posterior branch of the inferior ul** collateral.

It will be seen that the inferior ulnar collateral (anastomotica magna) is the artery most largely employed, distributing branches everywhere, save to the front of the lateral epicondyle.

THE FOREARM

Bony landmarks.—The *posterior border of the ulna* can be easily traced down from the olecranon to the back of the styloid process; the bone becomes somewhat rounded below, and lies between the flexor and extensor carpi ulnaris. The tip of the *styloid process* corresponds to the medial end of the line of the wrist-joint. The *radius* is covered above by the brachioradialis and radial extensors of the carpus, and the outline of the bone is less easily followed. Its *styloid process* is readily made out below a finger's breadth above the thenar eminence. It is placed about 1.2 cm. (½ in.) lower than that of the styloid process of the ulna.

FIG. 1125.—THE BRACHIAL ARTERY AT THE BEND OF THE ELBOW.
(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



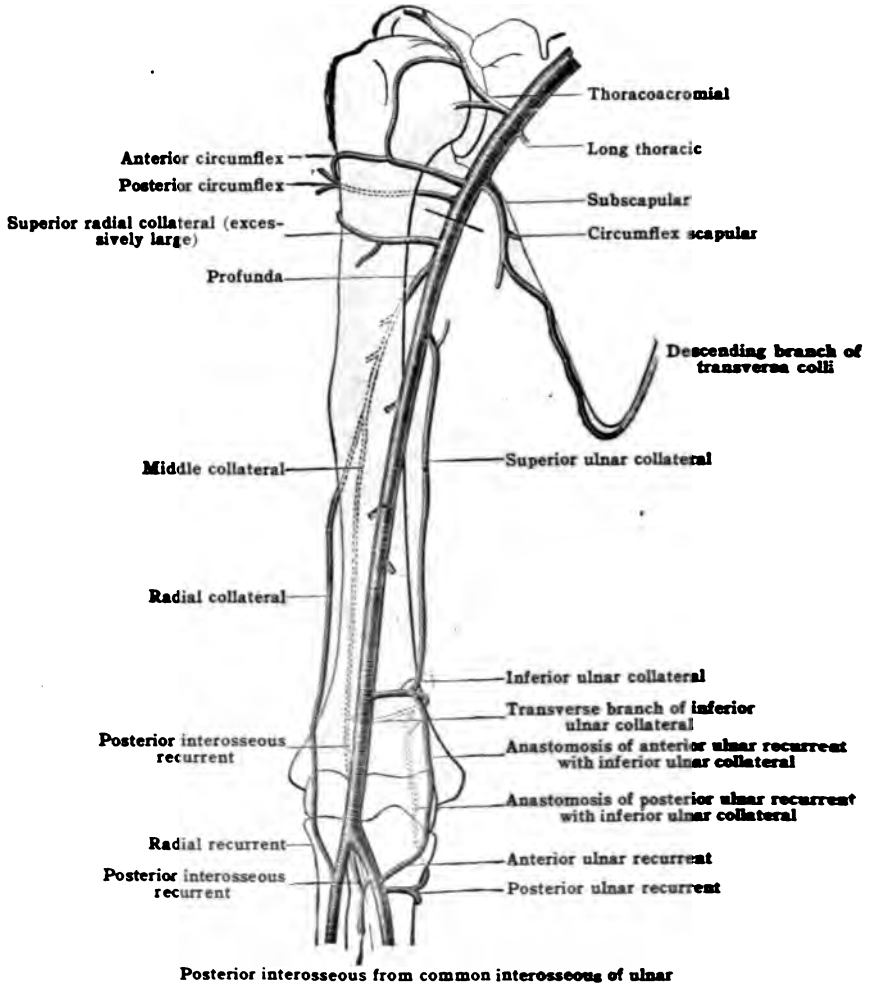
Thus, a line drawn straight between the two processes would fall a little below that of the wrist-joint, this being shown by a line drawn between the two processes forming a slight curve, with its concavity downward (corresponding to the concavity of the lower surface of the radius and fibrocartilage) about 1.2 cm. (½ in.) above the straight line given above

The radial styloid process is covered by the abductor longus and extensor brevis pollicis, while farther out lies the extensor pollicis longus. Between the styloid process of the ulna and the rounded head is the groove for the extensor carpi ulnaris. The bones are nearest to each other in complete pronation, and farthest apart in complete supination. On section (fig. 1129), the bones are found at every point nearer to the back than to the front of the limb, but increasingly so above. The lower the section proceeds down the limb, the less will the bones be covered at the sides, and the more equally will the soft parts be distributed about the anterior and posterior aspects of the limb. It will be noticed that where one bone is the more substantial, the other is the more slender, as near the elbow and wrist; and that it is about the center of the limb that the two are most nearly of equal strength. (Treves.) When the limb is pronated, the interosseous space is narrowed; in supination and the midposition it is widened out. In pronation, both styloid processes can be distinctly made out; in supination, that of the radius is the more distinct, as now the skin and soft parts are stretched and raised over that of the ulna.

Joints.—The position of the **superior radioulnar joint** is marked by a dim about 12 mm. (½ in.) below the lateral epicondyle. The **inferior** can just be f when the forearm is pronated, between the head of the ulna and lower end of radius. The recessus sacciformis here may be enlarged in rheumatic and ot affections. The **interosseous membrane** not only ties the bones together : gives attachment to muscles, but in falls on the hand it enables the ulna to part pate in the shock.

The following are important points with regard to the bones. *Common fractures. cranon.*—This usually takes place at the constricted center of the semilunar (greater sigm notch or the junction of the olecranon with the shaft. A fall is here the usual cause,

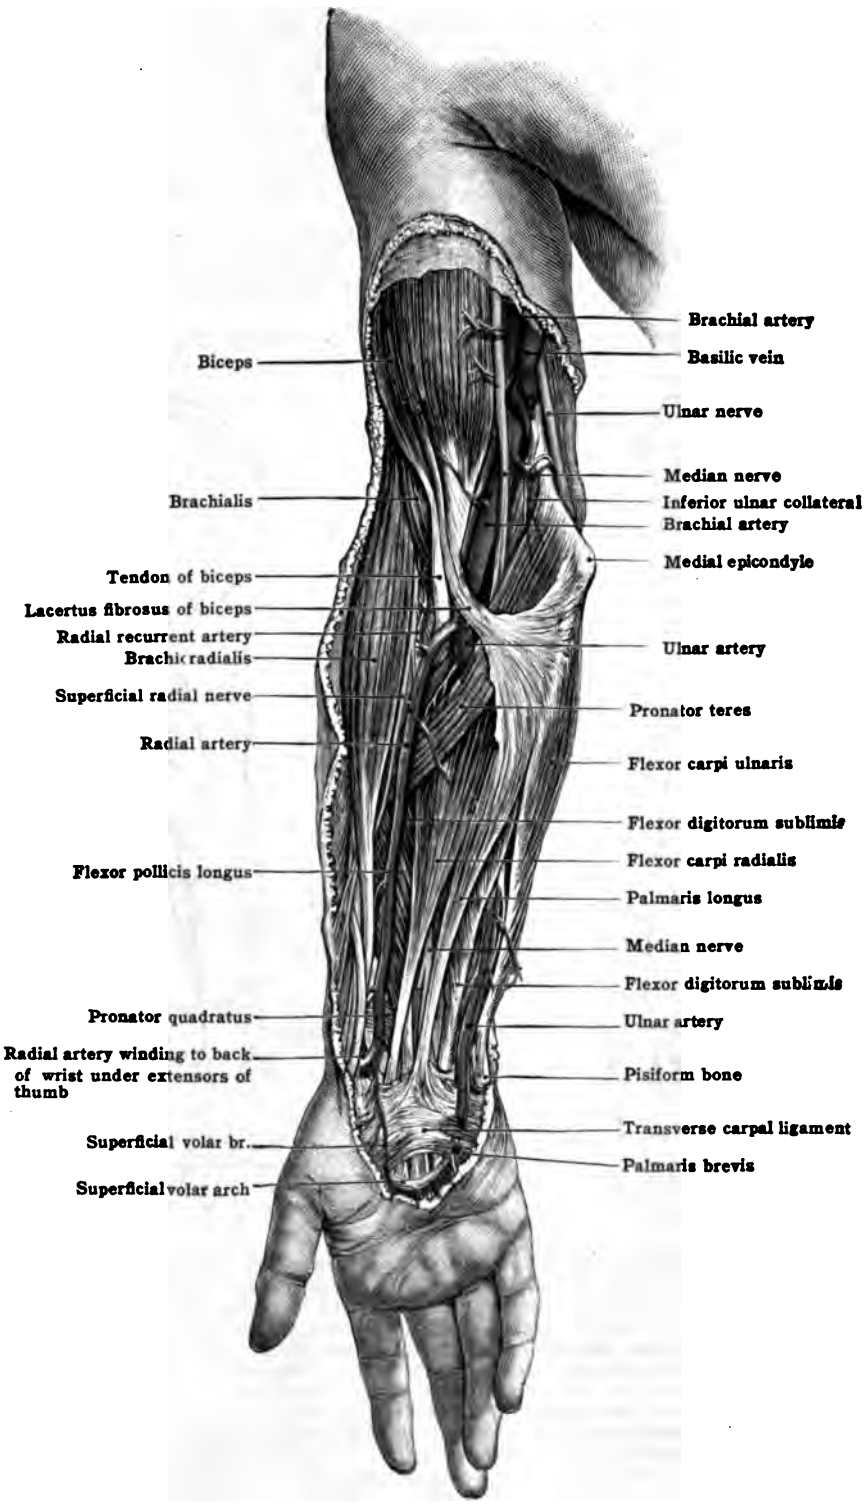
FIG. 1126.—DIAGRAM OF THE ANASTOMOSES OF THE BRACHIAL ARTERY. (MacCormac and Anderson.)



Posterior interosseous from common interosseous of ulnar

the heavier the fall, the more frequently is the fracture nearer the shaft, though displacem is now likely to be slight, owing to the abundance of fibrous and muscular structures on b sides of the fracture. *The shaft of one or both bones.* Usual site, about the middle or a li below it, fracture of the radius being more frequent from its connection with the hand. these fractures the chief muscular agencies are—(1) the extensors and flexors in drawing lower fragment or fragments upward, forward, or backward, according to the direction of fracture; (2) the biceps in drawing the upper fragment of the radius upward; (3) the influe of the pronator teres, if the fracture is, as usual, below it, and (4) that of the quadratus drawing the lower fragments together. Thus the chief practical points are—(a) the reduct of displacement, whether anteroposterior or lateral; (b) the greater the number of fragme the greater the tendency to union across the interosseous space, with its embarrassing resu and the greater the need of a supinated position in the setting; (c) the risk of gangrene h from the facility with which the vessels are compressed against the contiguous bones es cially in flexion of the forearm; and the consequent need of attention to the width of the spli

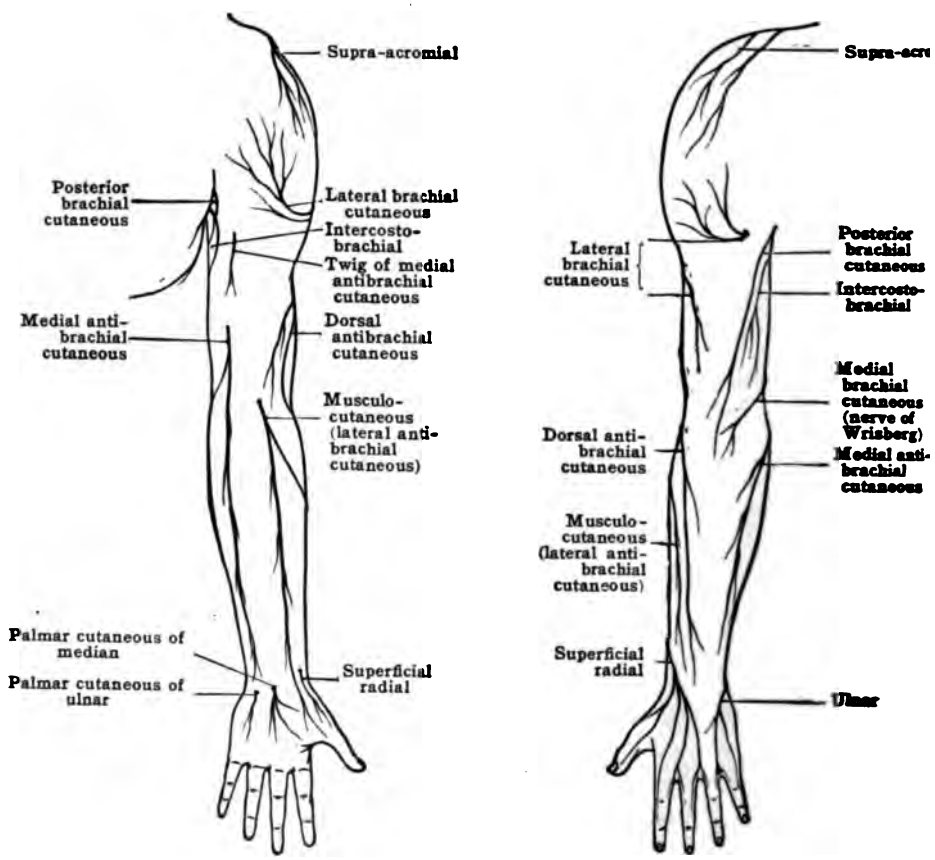
FIG. 1127.—THE MUSCLES AND ARTERIES OF THE FOREARM.



and the bandaging; (*d*) the readiness with which ischemic paralysis may rapidly and i iously be caused. It is a good rule to remember in treating fractures that the long frag which can be controlled should be dressed in line with the short fragment which cann controlled. The origins, insertion and actions of muscles on different fragments shou thoroughly understood if this principle is to be carried out. **Colles' fracture.** Here, a fall on the hand, the radius gives way usually at its weakest part, about 18 mm. (¾in.) its extremity, where the narrow compact tissue is suddenly expanding into cancellous. is frequently impaction of the upper into the lower fragment. There is a three-fold dis ment of the lower fragment:—(1) It is driven and drawn upward and backward. (2) rotated so that its articular surface looks somewhat backward. (3) It is drawn to the r side. The chief causes of the discreditable stiffness often allowed to result are non-redu of the deformity, adhesions in the opened wrist-joint, tenosynovitis, and prolonged i bilization.

Separation of epiphysis.—This may take place in the radius up to about the age of eigh it is commoner before. Its possible importance in interfering with the symmetry of the gr of the bones is obvious. Here, as in Colles' fracture, the level of the styloid processes o

FIG. 1128.—DISTRIBUTION OF CUTANEOUS NERVES ON THE ANTERIOR AND POSTERIOR ASP OF THE SUPERIOR EXTREMITY.



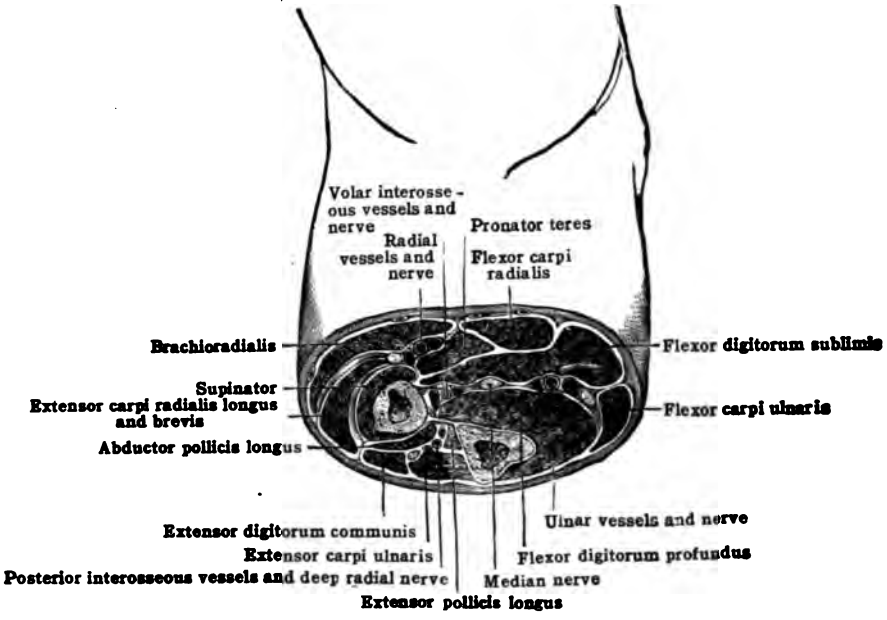
radius and ulna, and the relations of the two styloid processes to each other, are import in diagnosis. **Exposure of the bones.** In the case of ununited fracture or necrosis the ra may be reached—(*a*) *Behind*, by an incision in a line drawn from the lateral epicondyle to back of the radius. The field opened here lies between the brachioradialis and the ra extensors on the one side, and the common extensor on the other. Care must be taken of deep radial (posterior interosseous) nerve. (*b*) *In front.* The incision here lies in the su between the brachioradialis and the flexors. The pronator teres and the flexor sublimis m in part, be detached from the radius. If more room is required to reach an injured up extremity of the radius, the incision will descend from above the lateral epicondyle in the gro between the anconeus and common extensors. In the detachment of the supinator the d radial nerve will again need attention. The ulna is more easily reached by an incision betw the flexor and extensor carpi ulnaris. In removal of the lower part of the bones for mye sarcoma or osteitis, the ulna is reached in the interval last mentioned. The radius is l exposed by an incision between the brachioradialis and extensor carpi radialis longus, the su ficial radial nerve being the guide. (Morris.) Finally, the so-called 'carrying angle' of forearm deserves mention. In extension the bones of the forearm are not in a straight line v the humerus, but directed slightly laterally, the angle at the elbow-joint being obtuse, and o

laterally. This angle is so named from its facilitating carrying objects during walking. In flexion the forearm is deflected somewhat toward the middle line, mouth, etc. These properties are liable to be lost under many and widely different conditions, of which injuries to the epiphyses of the humerus, badly united fractures of the humerus (supracondylar) or forearm, and osteoarthritis of the elbow-joint are instances.

Soft parts (figs. 1127, 1129).—Along the lateral border, of the forearm descend the brachioradialis and radial extensors of the carpus, fleshy above, tendinous below. About 3.7 cm. (1½ in.) above the styloid process of the radius, a fleshy swelling directed obliquely downward and forward from behind, across this lateral border of the forearm, denotes the extensors of the thumb crossing those of the carpus.

Along the medial border is the fleshy mass of the pronator teres and flexors, the ulna being covered by the flexor carpi ulnaris and flexor profundus. The tendon of the pronator is inserted into the radius a little below its center—a point of importance in the treatment of fractures and in amputation. The flexor carpi ulnaris tendon can be felt just above the wrist making for the pisiform bone; and just lateral to it lies the **ulnar artery**, about to pass over the transverse carpal (anterior annular) ligament.

FIG. 1129.—SECTION THROUGH THE MIDDLE OF THE RIGHT FOREARM. (Heath.)



The course of the artery is denoted by the lower two-thirds of a line drawn from the front of the medial epicondyle to the lateral edge of the pisiform bone. From the bifurcation of the brachial, a line drawn to meet the former at the junction of its middle and upper third marks the upper part of the artery, here thickly covered by muscles. In **ligature of the artery** in *the middle* of the forearm, the white line and sulcus between the flexor carpi ulnaris and sublimis must be identified. A small muscular branch will often lead down to the artery. The line of the **ulnar nerve** is one drawn from the interval between the medial epicondyle and the olecranon to the medial side of the ulnar artery just above the wrist. The nerve joins the artery at the junction of the upper and middle thirds of the forearm. The **median nerve** runs in a line drawn from the medial side of the brachial artery, in the elbow triangle, to a point beneath, or just to the medial side of, the palmaris longus at the midpoint of the front of the wrist. The **radial artery** will be marked by a line drawn from the center of the bend of the elbow (where the brachial artery divides opposite the neck of the radius) to a point just medial to the radial styloid process descending along the medial edge of the brachioradialis. The muscular interval is that between the brachioradialis and pronator teres above, and the flexor carpi radialis below. The **superficial radial nerve** will be marked by the same line (it lies just lateral to the artery) for its upper two-thirds; it then leaves the artery about 7.5 cm. (3 in.) above the wrist-joint, and passes to the back of the forearm under the tendon of the brachioradialis. The **volar interosseous artery** runs down on the interosseous membrane and passes to the back of the forearm by perforating it below, having passed behind the pronator quadratus. The **dorsal interosseous** lies between the superficial and deep extensors. These small arteries reinforce the palmar through the carpal arches, and thus bring down blood after ligature of the trunks above.

being produced (see fig. 1130, A). **Sensation** will be lost over the palmar aspect of the thumb and lateral two and one-half fingers and over the distal ends of the same fingers, to a varying degree, according to the sensory distribution of the median and other cutaneous nerves. The above applies to lesions of the trunk. If the nerve be injured at the wrist, flexion of the wrist and fingers is less interfered with.

Paralysis of the ulnar nerve.—(*a*) *At wrist:* Power of flexion is diminished and that of ulnar adduction lost. (*b*) *In the hand:* Power of grasp will be lessened in the ring and little fingers. The interossei will be powerless to abduct or adduct the fingers, and there will be marked wasting of the interosseous spaces and hypothenar eminence. The thumb cannot be adducted. After a time, from paralysis of the lumbricals and interossei, the hand becomes 'clawed'—the first phalanges overextended, and the second and third flexed (**main en griffe**). (See fig. 1130, B.) Sensation will be lessened over the area supplied by the nerve.

Paralysis of the radial (musculospiral) nerve.—(*a*) *In the forearm:* This is flexed, extension being impossible The forearm is pronated, supination being impossible save by biceps, which acts now most strongly on a flexed elbow-joint. (*b*) *In the wrist:* This is dropped, owing to the loss of extension. (*c*) *In the hand:* The thumb is flexed and adducted. Some slight power of extension of the second and third phalanges of the fingers remains by means of the lumbricales and interossei. (See fig. 1130, D.) **Sensation** is impaired over the posterior and lateral aspect of the forearm and lost to a varying extent over the distribution of the radial on the back of the hand.

Paralysis of the deep radial (posterior interosseous) nerve.—The evidence here is somewhat similar to that just given, but with the following differences. (*a*) *In the forearm:* There is no loss of extension, and the loss of supination is less as the brachioradialis is not paralysed. (*b*) *At the wrist:* The 'drop' and loss of extension are not so marked, as the extensor carpi radialis longus escapes. **Sensation:** There is no loss.

Paralysis of the musculocutaneous nerve.—*Forearm:* Power of flexion is impaired, owing to complete paralysis of the biceps and partial of the brachialis (anterior). **Sensation:** This is impaired over the lateral aspect of the forearm, both back and front.

The **lymphatics of the upper extremity** are **superficial** and **deep**; the former run with the superficial veins, the latter with the deep vessels. Occasionally a few small **nodes** occur below the elbow. The epitrochlear nodes lie upon the basilic **vein**, a little above the medial epicondyle and drain the fourth and fifth digits. The majority of the lymphatics open into the axillary nodes, and terminate, on the left side in the thoracic duct, on the right in the lymphatic duct. A few, accompanying the cephalic vein, reach the subclavian or infraclavicular nodes, and thus communicate with the lymphatics of the neck.

Amputation of forearm.—The 'mixed' method by skin-flaps roundly arched and circular division of the soft parts, the dorsal flap being the longer, is the most generally applicable. The bones should always be sawn below the pronator teres, when possible. In sawing them they must be kept parallel, the limb being in the supinated position. As the radius is the less securely held above, it is well to complete the section of this bone first. The relative position of the vessels has been indicated above (p. 1423, and figs. 1127 and 1129).

THE WRIST AND HAND

Bony points.—On the medial side the *styloid process* and, further laterally, the *head of the ulna* can be made out. On the lateral side, the *radial styloid process* descends about 1.2 cm. ($1\frac{1}{2}$ in.) lower than that of the radius, and is somewhat anterior to it. Abduction of the hand is thus less free than adduction. Between the apex of the styloid process and the ball of the thumb a bony ridge can be felt, with some difficulty, formed by the *tubercle of the navicular* and the ridge of the *greater multangular* (trapezium). At the base of the hypothenar eminence the *pisiform* can be more readily distinguished. The *hook of the hamatum* (unciform) lies below and to the radial side of the pisiform. On the front of the metacarpophalangeal joint of the thumb, the *sesamoid bones* can be distinguished.

At the back of the wrist and hand the *triquetrum* (cuneiform) bone can be felt below the head of the ulna; and more toward the middle line the prominence of the *capitatum* (os magnum), which supports the third or longest digit.

A line drawn from the base of the fifth metacarpal bone to the radiocarpal joint, slightly curved downward, will give the line of the carpometacarpal joints. (Windle.) When the fingers are flexed, it will be seen that in each case it is the proximal bone which forms the prominence; thus, the knuckle is formed by the head of the metacarpal, the interphalangeal prominence by the head of the first phalanx, and the distal one by the head of the second. Thus, the joint in each case lies below the prominence, the distal joint being 2 mm. ($^1/_{12}$ in.), the interphalangeal 4 mm. ($^1/_6$ in.), and the metacarpophalangeal 8 mm. ($^1/_3$ in.) below its prominence.

Skin and skin-folds.—The *skin* over the palm is thickened over the heads of the metacarpal bones and hypothenar eminence, thinner over the thenar. It is peculiar in its absence of sebaceous glands and hair-follicles; hence the absence of

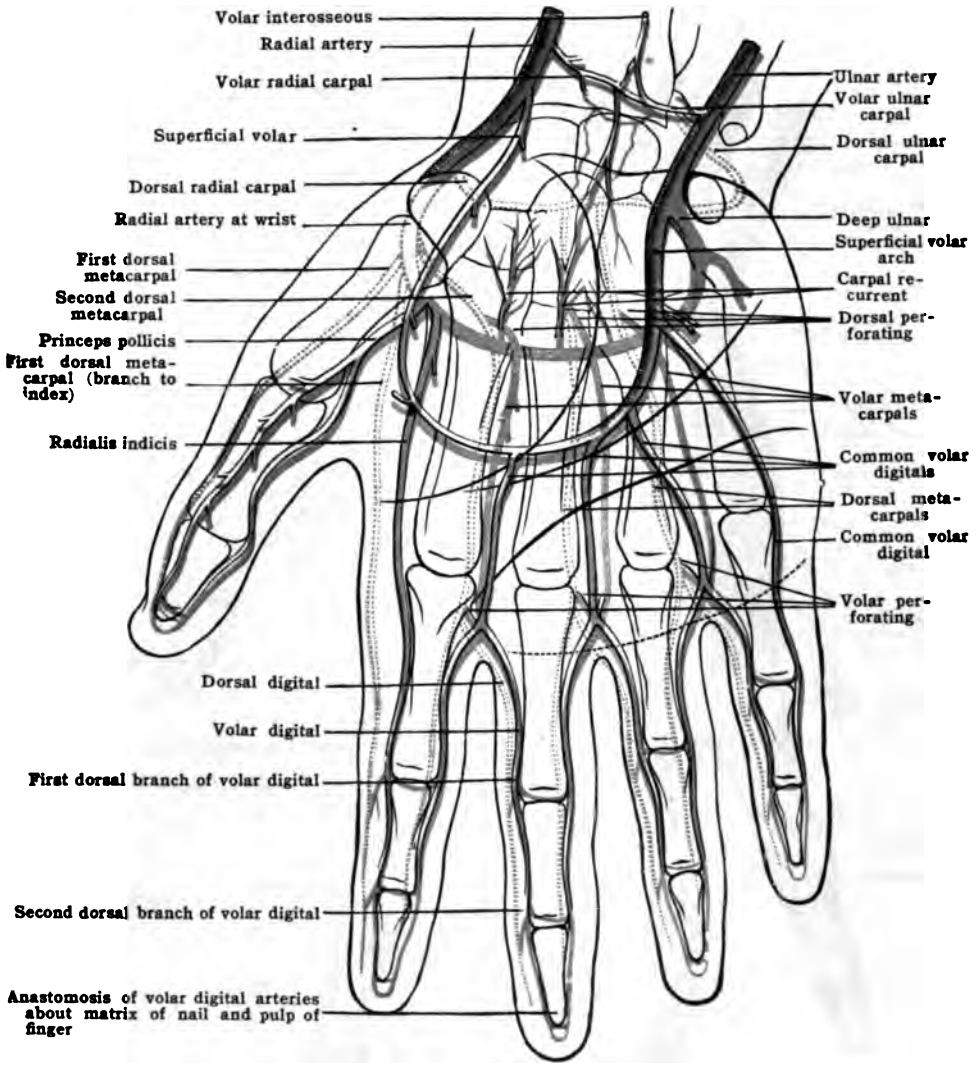
ligament does not bifurcate.

The digital arteries then descend along the sides of the fingers under the digital nerves, giving off twigs to the sheath of the tendons, which enter by apertures in it, and run in the vincula vasculosa. It is owing to the readiness with which these tiny twigs are strangled by inflammation that sloughing of the tendon takes place so readily and irreparably. Throughout its course the superficial volar arch deserves its name. It is only covered by the palmaris brevis and central part of the palmar fascia. Beneath it, mediolaterally are the flexor brevis and opponens digiti quinti, the digital branches of the ulnar and median nerves, and the flexor tendons and lumbricales.

FIG. 1132.—ANASTOMOSES AND DISTRIBUTION OF THE ARTERIES OF THE HAND.



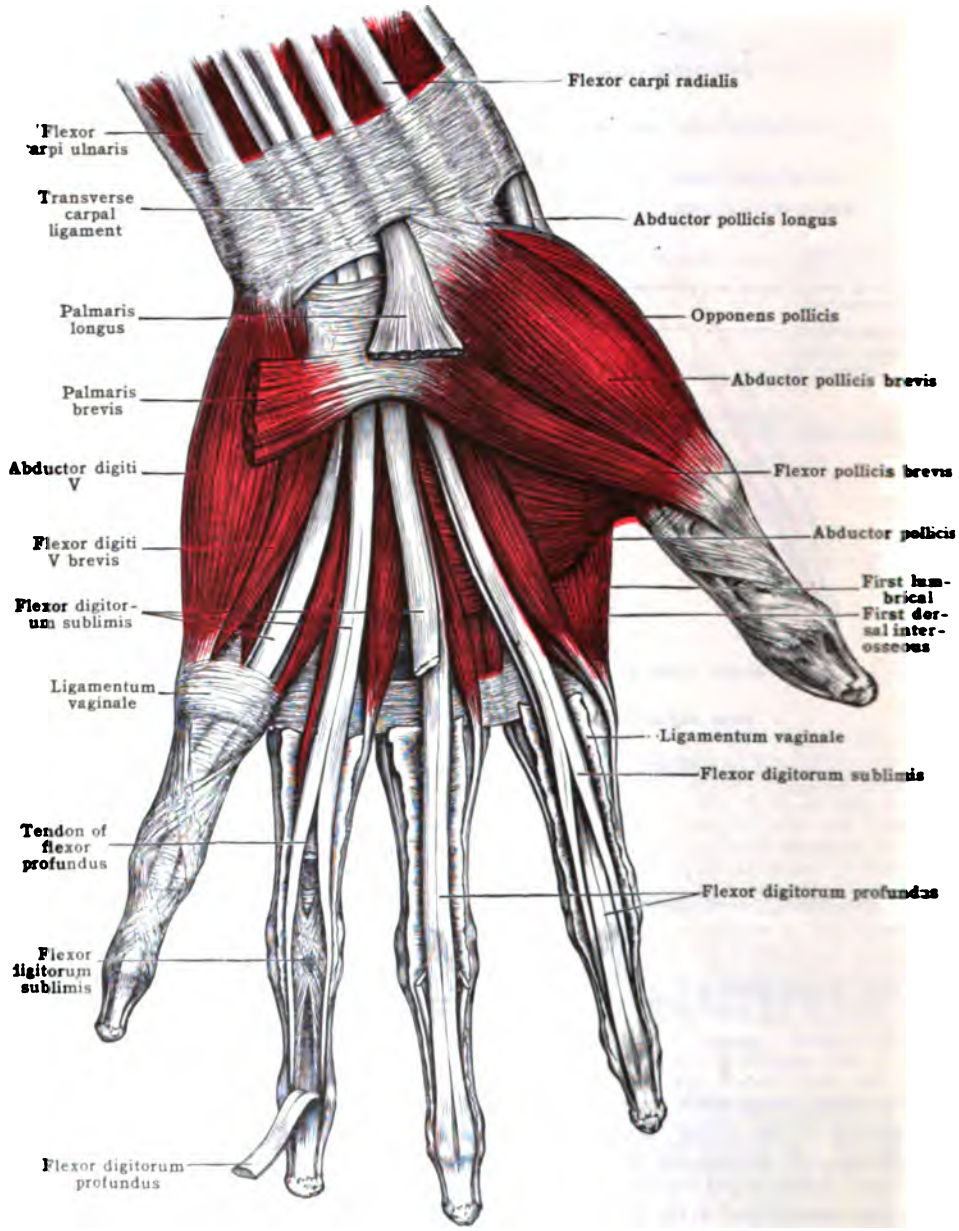
The **deep volar arch** (figs. 1131, 1132), formed by the radial and communicating branch of the ulnar, lies about 1.2 cm. (½ in.) nearer to the wrist than the superficial. It is not so curved as the superficial arch, and rests upon the interossei and metacarpal bones just below their bases. The structures separating it from the superficial arch have been already given.

Owing to the frequency of wounds here, the relation of the **structures in front of the wrist** (fig. 1135) is most important. The radial artery lies between the tendon of the brachioradialis and flexor carpi radialis. Next to this tendon is the palmaris longus, when present. At the midpoint of the front of the wrist and usually under the palmaris longus is the median nerve. To the medial side of the palmaris longus is the flexor sublimis, the tendons for the middle and ring-finger being in front. The tendon of the flexor carpi ulnaris is most medial and between

this and the superficial flexor of the finger the ulnar nerve and vessels have come up into a superficial position.

Fasciæ and sheaths.—The transverse and dorsal carpal (annular) ligaments bind down and hold in place the numerous tendons about the wrist. The **transverse carpal** (anterior annular), when healthy, cannot be detected. It is attached to the pisiform and triquetral (cuneiform) bones on the medial, and to the navicular and greater multangular (trapezium) on the lateral, side (figs. 1133, 1137).

FIG. 1133.—THE SUPERFICIAL MUSCLES OF THE PALM OF THE HAND.

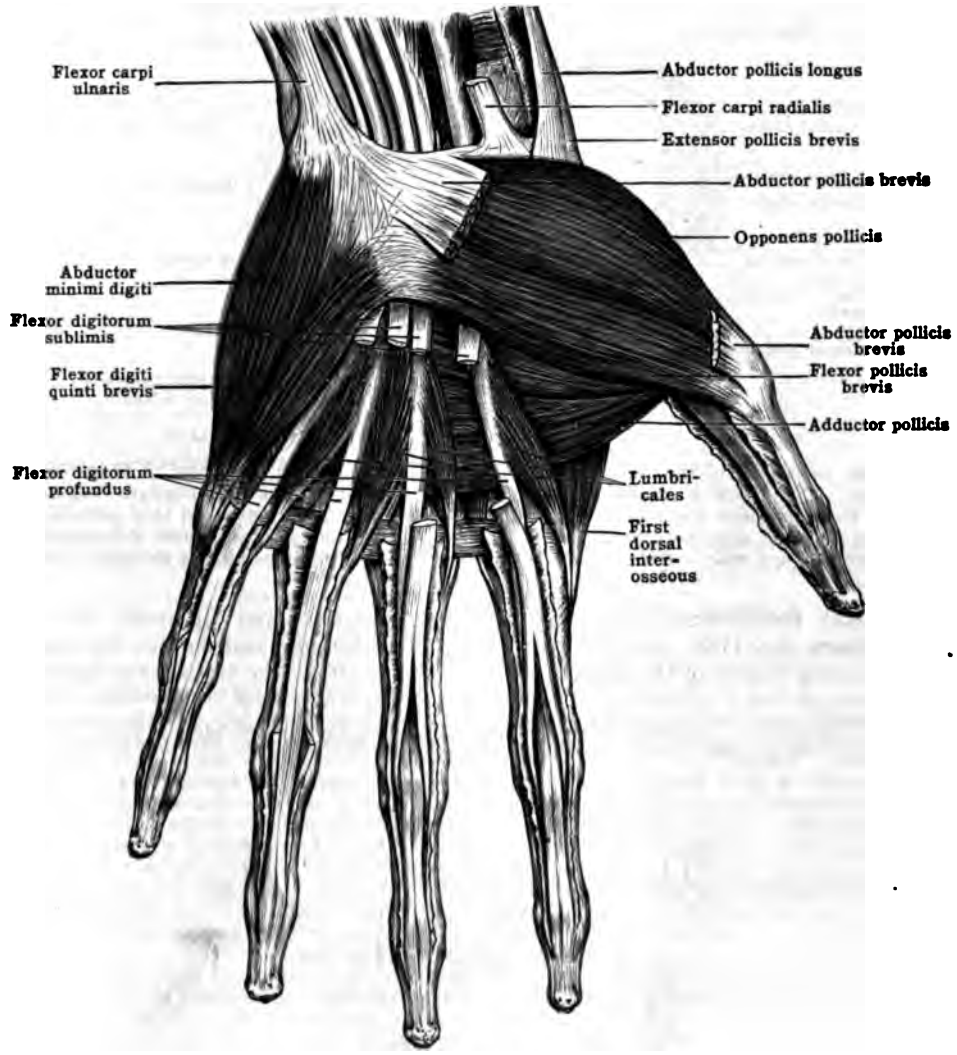


The ulnar nerve and vessels, the superficial volar, and palmar cutaneous branches of the median and ulnar pass over the transverse carpal ligament. The ulnar artery and nerve are especially protected by their position between the pisiform and hook of the hamate (unciform), and also by a process of the flexor carpi ulnaris, which passes to the transverse ligament, thus forming a kind of tunnel. The flexor carpi radialis passes through a separate sheath formed by the ligaments and the groove in the greater multangular; while beneath the ligaments lie the flexor tendons, the median nerve, and accompanying artery. Attached to its upper border

is the deep fascia of the forearm, and to its lower the palmar fascia and the palmaris longus tendon, while from the lateral and medial parts arise some of the thenar and hypothenar muscles. The upper border of the transverse carpal ligament corresponds to the lower of the two lines which cross the wrist just above the thenar and hypothenar eminences. The large synovial sheath, for all the flexors of the fingers, reaches beneath and below the transverse ligaments as far as the middle of the palm, and above the wrist for 3.7 to 5 cm. (1½ to 2 in.)

The **dorsal carpal** (posterior annular) **ligament** is attached to the back of the lateral margin of the radius above the styloid process, and medially to the back of the styloid process of the ulna, the triquetrum and pisiform. Its direction is oblique, being higher on the radial side. It contains six tendon-compartments, of which four are on the radius (figs. 1135, 1138).

FIG. 1134.—THE DEEPER MUSCLES OF THE PALM OF THE HAND.

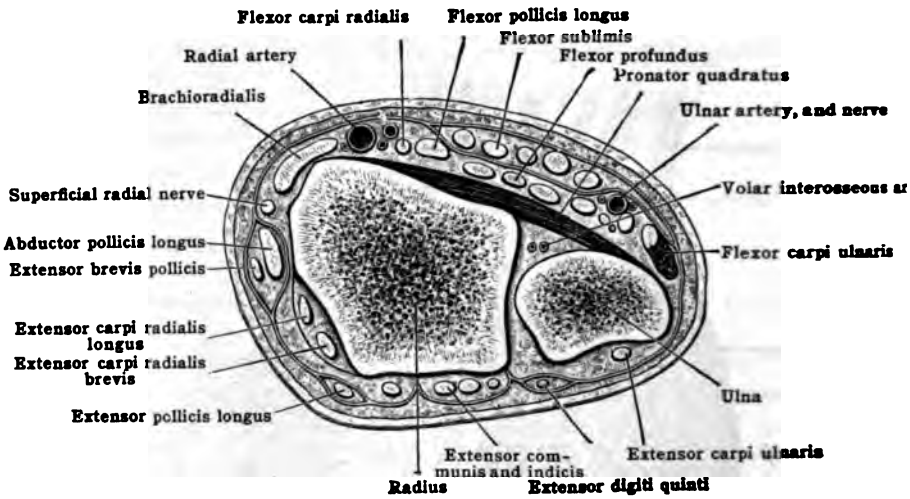


The most lateral contains the long abductor and short extensor of the thumb; the second the two radial extensors of the carpus; the third, the extensor pollicis longus; this deep and narrow groove can be identified when the hand is extended, by its prominent lateral margin; the fourth transmits the extensor communis and extensor indicis proprius; the fifth, lying between the radius and ulna, the extensor digiti quinti; and the sixth, lying just lateral to the styloid process of the ulna, the extensor carpi ulnaris. The sheaths for the last two extensors are the only ones which follow the tendons of their insertion, the others ending at a varying distance below the carpal ligament. The lower border of the dorsal carpal corresponds to the upper margin of the transverse carpal ligament.

The **palmar aponeurosis,** by its strength, toughness, numerous attachments, and intimate connection with the superficial fascia and skin is well adapted to protect the parts beneath from pressure.

The thenar and hypothenar muscles are enclosed in two processes, which are thinner not to interfere with the contraction of the subjacent muscles. The central part, pointed at its attachment to the carpal ligament, spreads out fan-like below, and gives off four each of which bifurcates into two processes, which are attached to the sides of the first ph of each finger and into the superficial transverse ligament of the web and the deeper one ties the heads of the metacarpal bones together. Transverse fibers pass between the pro into which each of the four slips bifurcates, and thus form the beginning of the theca, wh continued down the finger to the base of the last phalanx. It is the contraction of the p

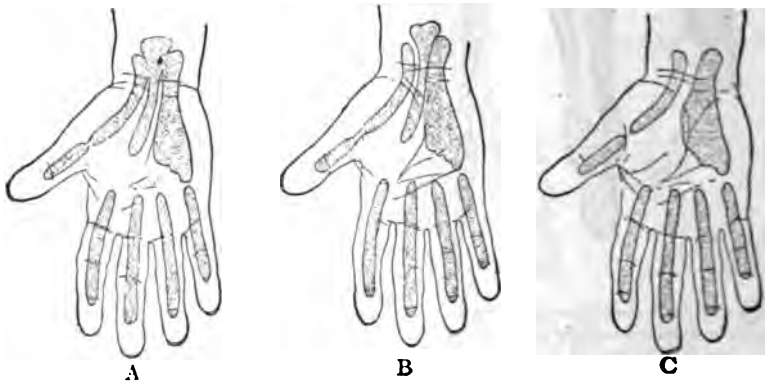
FIG. 1135.—SECTION THROUGH REGION OF WRIST, A LITTLE ABOVE THE JOINT. RIGHT UPPER HALF OF THE SECTION. (Tillaux.)



aponeurosis, especially of the slip to the two medial fingers, which gives rise to Dupuyt contraction. The theca is strong opposite the first two phalanges (ligamentum vagin weak and loose opposite the joints (ligamentum annulare). The density of this osseofib tunnel and its close proximity to the digital nerves explain the pain in thecal inflamma Its tendency to gape widely after section is to be remembered in amputations through infe parts.

Synovial membranes.—Beneath the transverse carpal ligament lie **synovial sacs** (fig. 1136), one for the flexor pollicis longus, and one for the su ficial and deep flexors of the fingers. They extend above the transverse ligam

FIG. 1136.—SYNOVIAL SHEATHS OF THE TENDONS OF THE LONG FLEXORS OF THE FING After Poirier and Charpy. A. Frequent type; B. Normal type; C. Fetal type.



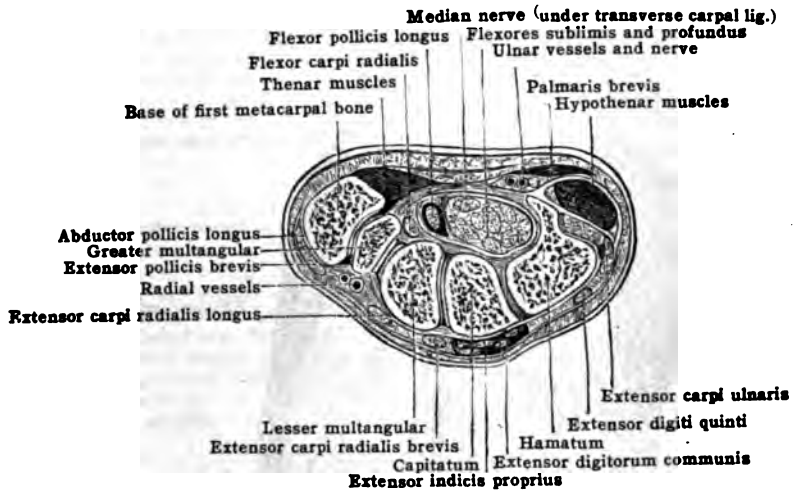
for rather more than 2.5 cm. (1 in.). The two sacs may communicate. A c pound palmar 'ganglion' has an hour-glass outline, the transverse carpal ligam forming the constriction.

The creaking sensation in tenosynovitis and that of 'melon seed' bodies often presen tuberculosis here is well known. The sheath for the long flexor of the thumb reaches to base of the last phalanx. That for the finger-flexors gives off four processes. The one for

little finger also reaches to the base of the last phalanx. Those for the index-, middle, and third fingers end about the middle of the metacarpal bones. Traced from the insertions of the flexor profundus, the digital synovial sheaths extend upward into the palm as far as the bifurcation of the palmar fascia (p. 1430), i. e., to a point about opposite to the necks of the metacarpal bones, denoted on the surface by the crease which corresponds to the flexion of the fingers. Thus, about 1.2 cm. (½ in.) separates the sheaths of the lateral three fingers from the large synovial sac beneath the transverse carpal ligament. There is no synovial sheath beneath the pulp of the fingers or thumb, this part lying on the periosteum of the last phalanx.

This has an important bearing on **whitlow.** Infection here may be merely *subcutaneous*, or deeper, in the latter case from the connection of the skin with the periosteum here existing the bone is soon affected, and necrosis keeps up a tedious ulcer. As the two centers of the phalanx do not unite till about the twentieth year, the distal one only requires removal; as the flexor sheath only reaches to the insertion of the flexor, i. e., into the proximal, part of the bone, both sheath and tendon may escape implication. Higher up along the fingers whitlow may be *cellulocutaneous* or *synovial.* While the continuity of the synovial sheath in the little finger and thumb (fig. 1136) renders infection here more dangerous, the short gap between the digital and the palmar sacs is readily traversed by acute infection, with all the grave results of synovial suppuration.

FIG. 1137.—SECTION OF CARPUS THROUGH THE HAMATE BONE. (× ⅔.) (Bellamy, after Henle.)



Suppuration in the hand owes much of its gravity to the possibility of infection of the synovial tendon sheaths and consequent sloughing of the tendons. At the same time it is now recognized that unless these sheaths are primarily infected pus collects at first in certain potential spaces, more or less well defined, in the looser connective tissue of the hand. One of these known as the **middle palmar space,** (Kanavel: Infectons of the Hand, 1912) is situated on the front of the metacarpals of the middle and ring fingers, and lies deeply between the flexor tendons and the interosseous muscles. Continuations of this potential space extend downward along the lumbrical muscles on the radial side of the three medial fingers, and may lead pus from the palm to the subcutaneous tissue of these fingers or *vice versa.* A second potential compartment, the **thenar space** (Kanavel) lies in front of the index metacarpal, between the flexors of the index-finger and the adductor transversus pollicis.. As in the former space, the corresponding lumbrical muscle prolongs it down to the radial side of the index-finger.

Distention of the middle palmar space with pus leads to obliteration of the hollow of the palm and a variable extension of the swelling along the radial side of the three medial fingers. Distention of the thenar space follows the thenar eminence, obliterates the adduction crease of the thumb, and may extend down the radial side of the index-finger. There is not in either case the extreme tenderness and pain on passive extension of the fingers that is characteristic of infection of the synovial sheaths. The pus is best evacuated by an incision on the radial side of the finger most affected, a little behind the web, sinus forceps being passed along the lumbrical muscle into the palm, so as to avoid opening and infecting the synovial sheaths.

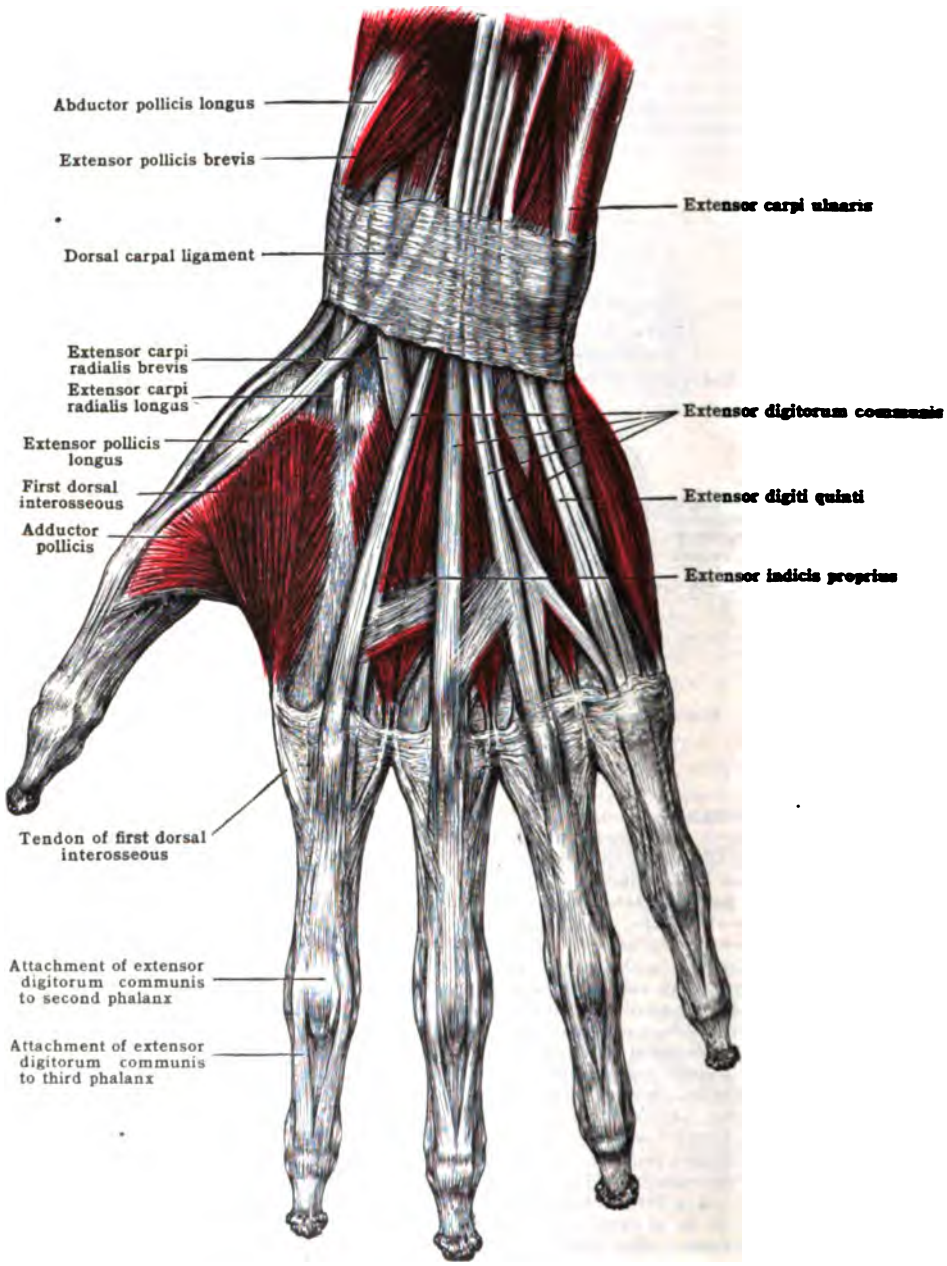
It must be remembered also that infection of the above fascial spaces may take place secondarily, by the bursting into them of pus from the synovial tendon sheaths.

Deeper are the **articular synovial sacs** (fig. 337) five in number:—(1) Between the interarticular cartilage and the head of the ulna; (2) between the radius and the interarticular cartilage above, and the navicular and lunate and triquetrum below; (3) between the greater multangular and first metacarpal bone; (4) between the pisiform and the triquetral bone; (5) between the two rows of carpal bones, sending two processes upward between the three bones of the upper row,

and three downward between the four of the lower row; these three processes being also continued below into the medial four carpometacarpal and three intermetacarpal joints.

Beneath the palmar aponeurosis covering the *thenar eminence* are the following structures:—Superficial volar artery, abductor pollicis brevis, opponens pollicis, radial head of short flexor,

FIG. 1138.—TENDONS UPON THE DORSUM OF THE HAND.



tendon of long flexor, ulnar head of short flexor, first volar metacarpal arteries, metacarpal bone of the thumb, with the tendon of the flexor carpi radialis and greater multangular.

Beneath the *central part* of the palmar aponeurosis are the superficial arch and its digital branches; the ulnar and median nerves, with their branches; the flexors, superficial and deep, with their synovial sheath; and the lumbricales; then a layer of connective tissue (the only structure, together with the deep layer of fascia over the interossei, which prevents matter pent in by the palmar aponeurosis from making its way back out through the dorsum), the deep arch, the interossei, and the metacarpal bones.

In the *hypothenar eminence* under the fascia are part of the ulnar artery and nerve, the abductor and flexor brevis digiti quinti, the opponens, the deep branch of the ulnar artery and nerve, and the fifth metacarpal bone.

The back of the wrist and hand (fig. 1138).—The dorsal carpal (posterior annular) ligament has already been described. On the lateral side is the so-called 'snuff-box space' (*tabatière anatomique* of Cloquet), a triangular hollow, bounded toward the radius by the long abductor and short extensor of the thumb, and toward the ulna by the long extensor. The navicular and greater multangular, with their dorsal ligaments, form the floor. In the roof lie the radial vein and branches of the radial nerve. More deeply is the artery, following a line from the apex of the styloid process to the back of the interosseous space.

The different tendons have already been given. Between the first two metacarpal bones is the first dorsal interosseous muscle, which forms a fleshy projection against the radial side of the index metacarpal, when the thumb and index are pressed together. On its palmar aspect is the adductor pollicis. Wasting of the former muscle is a ready indication of injury or disease of the ulnar nerve.

The skin on the dorsum, by its laxity, readily allows of edema, this being sometimes evidence of pressure on the axillary vein by carcinomatous deposits. The dorsal venous arch receives the digital plexuses, and from it the radial and posterior ulnar veins ascend. The median vein begins in plexuses at the root of the thumb and the front of the wrist.

Ganglia are common on the dorsum, in connection with the extensors of the fingers and the thumb. While usually due to a weakening of the sheath and protrusion of this and the synovial membrane, such swellings may be due to a projection of the articular synovial membrane. Owing to the laxity of the skin, the slight vascularity, the size of the tendons, their connection with joint-capsules and with each other, which fixes them, the dorsum of the wrist is the 'seat of election,' for **tendon-anastomosis** and other operations. **Metacarpophalangeal dislocation** occurs in the thumb and the index-finger especially. The chief cause in the difficulty in reduction is the accessory volar (glenoid) ligament. This, in reality a fibrocartilaginous plate, is blended with the lateral ligaments on the palmar aspect of the joint, and is firmly attached to the phalanx, but more loosely to the metacarpal. Thus when dislocation occurs in violent hyperextension, the metacarpal attachment of the glenoid ligament gives way and it is carried by the phalanx over the head of the metacarpal bone. In the case of the thumb, the buttonhole-like slit with which the two heads of the flexor brevis, now displaced, embrace the head of the metacarpal, renders reduction difficult. The contraction of the other short muscles, and, occasionally, a displaced long flexor, are additional causes of difficult reduction. In the case both of the thumb and finger, tilting the phalanx well back on the dorsum of the metacarpal and then combined pressure with the thumbs forward against the base of the phalanx, when this is sharply flexed, will with an anesthetic, be usually successful in effecting reduction. The thumb should be, first, adducted into the palm.

THE LOWER EXTREMITY

The various segments of the lower extremity will be successively considered as follows: hip and thigh, knee and leg, ankle and foot.

HIP AND THIGH

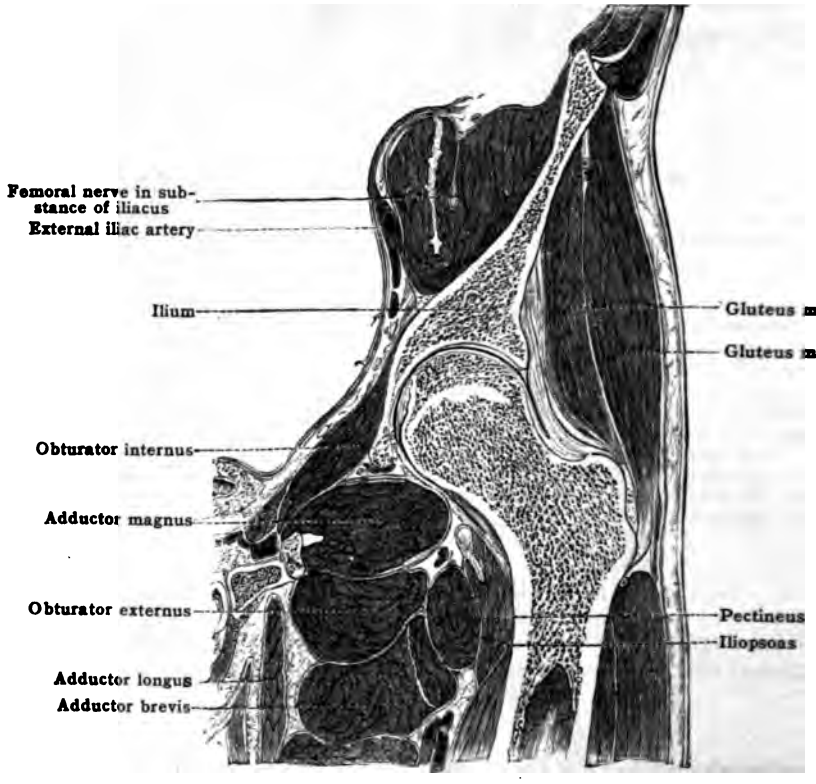
Bony landmarks.—Many of these, such as the anterior superior iliac spine and crest of the ilium and the pubic tubercle, have already been mentioned. The relative length of the limbs is obtained by carrying the measure from the anterior superior spine to the tip of the corresponding medial malleolus. The pelvis must be horizontal and the limbs parallel.

The head and shaft of the **femur** are well covered in, save in the emaciated. The head lies just below Poupart's ligament, under the iliopsoas, and a little to the lateral side of the center of that ligament. A line drawn horizontally laterally from the pubic tubercle will cross the lower part of the head. All the head and the front of the neck, but only two-thirds of the back, are within the capsule; this intracapsular position of the upper epiphysis, which, appearing at the first year, does not unite till eighteen or twenty, accounts largely for the extreme gravity of acute epiphysitis here. The structure of the neck, i. e., the two sets of lamellæ, *vertical* to support the weight, *transverse* and *intersecting* in order to meet the pull of the muscles, and the wasting of these after middle life, has an important influence on injuries. The strong process, *femoral spur* or *calcar* (Merkel) which, arising from the compact tissue on the medial and under side of the neck, just above the lesser trochanter, spreads laterally toward the trochanteric (digital) fossa, also affords strength, and its degeneration probably plays an important part in the fractures of the neck.

Hip-joint (figs. 339, 341, 343, 1139).—The chief points of surgical importance are the following:—The capsule shows fibers chiefly longitudinal in front, circular behind. Of the former, the iliofemoral or inverted Y-shaped ligament descends

from the anterior inferior spine to the two extremities of the anterior inte
chanteric line. It not only checks extension and strengthens the front o
joint, but it keeps the pelvis and trunk propped forward on the heads of the fe
thus preventing waste of muscular action. It is joined on the medial side b
pubocapsular ligament, which checks abduction. Between the two is the m
part of the front capsule, and here the iliopsoas bursa may communicate wit
joint. This fact must be remembered in tuberculous disease of the psoas.
the presence of this bursa explains certain deep-seated swellings in the front c
joint in adults. Behind, the ischiofemoral is the strongest part of the cap
its fibers blending with the circular and weaker part of the capsule here. I
cation usually occurs at the posterior, lower and medial part of the joint. It

FIG. 1139.—FRONTAL SECTION OF THE HIP-JOINT AND ITS RELATIONS. (×⅓) (Braune.)



be noted that in full extension and flexion the head of the femur is in contact w
the weakest spot in the capsule, in front and behind, respectively. From
deep aspect of the capsule fibers pass up at the line of reflection of the syno
membrane on to the neck—the retinacula (cervical ligaments of Stanley).
intracapsular fracture these fibers keep the fragments together; hence one n
of gentle handling; their softening may explain, a little later, an increase in
shortening.

Exploration of the joint.—This is usually effected by an oblique incision downward
slightly medially between the sartorius and rectus medially and the gluteus medius and mini
laterally. A branch of the ascending division of the lateral circumflex is the only artery
with. In tapping the joint the puncture is made in the same line, 2 or 3 inches below
anterior superior spine. If the instrument is pushed upward, medially, and backward ben
the rectus, it will pass into the joint a little above the anterior intertrochanteric line. (St

Trochanter major.—This valuable landmark is most prominent when the l
is rotated medially or adducted; it lies at the bottom of a depression when
femur is everted.

The chief structure of importance between it and the skin is the upper part of the inser
of the gluteus maximus, that going to the fascia lata, and the bursa beneath the muscle. Th

often multilocular. It is, not very uncommonly, the seat of tuberculous inflammation which readily invades the cancellous tissue of the trochanter. The top of the great trochanter is about 1.8 cm. (¾ in.) below the level of the femoral head, and, when the femur is extended is a little below the center of the hip-joint. This part of the bone is covered by the gluteus medius. The slightness of the prominence of the great trochanter in the living subject compared with that in the skeleton is explained by fig. 1139, which shows how the descending gluteus medius and minimus fill up the space between the ilium and trochanter. To examine the great trochanter, the thigh should be abducted, so as to relax the strong fascia lata passing upward over the tensor and glutei to the iliac crest.

Nélaton's line.—This useful guide is a line drawn from the anterior superior spine of the ilium to the most prominent part of the tuberosity of the ischium. In normal limbs, the top of the great trochanter just touches this line. In dislocation, fractures of the neck, and in wasting of the neck, as in osteoarthritis, the relation of the trochanter to Nélaton's line becomes altered.

The top of the great trochanter is a guide in Adams's operation for division of the neck of an ankylosed femur, the puncture being made and the saw entered 2.5 cm. (1 in.) above and about the same distance in front of this point. Owing to the fact that in many cases of ankylosis the neck is destroyed, the above operation has been largely replaced by the simpler and more widely applicable Gant's osteotomy just below the great trochanter, from the lateral side.

Bryant's triangle.—Bryant makes use of the following in deciding the position of the great trochanter. The patient being flat on his back (1) a line is dropped vertically on to the couch from the anterior superior spine; (2) from the top of the great trochanter a straight line in the long axis of the thigh is drawn to meet the first; (3) to complete the triangle, a line is drawn from

the anterior superior spine to the top of the trochanter. This line is practically Nél
The second line will be found diminished on the damaged or diseased side.

Muscular prominences (figs. 442, 1141).—The *tensor fasciæ latæ* forms a prominence
ning just lateral to the sartorius and reaching downward and somewhat backward to the
fascia lata, 7.5 to 10 cm. (3 to 4 in.) below the great trochanter. Below this point, as far
lateral condyle of the tibia, the strong *iliotibial band* can be felt. Like the inverted Y-
ligament, this band is a powerful saving of muscular action in maintaining the erect po
At the insertion of the tensor fasciæ latæ it bifurcates into two layers, which enclose the n

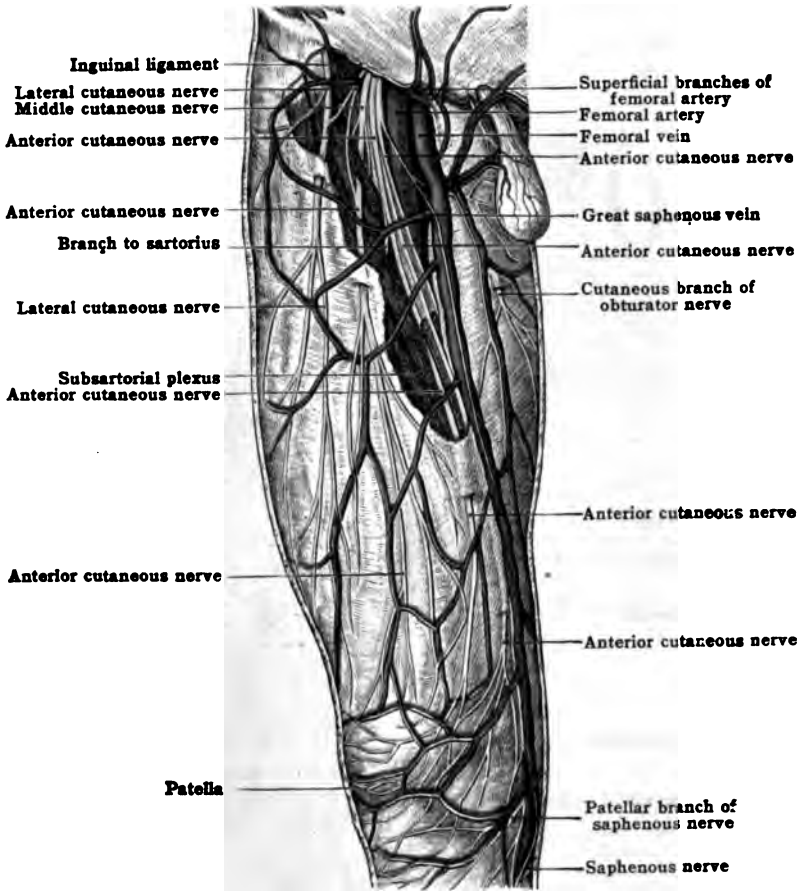
side below, above the knee-joint, the vertical fibers of the *adductor magnus* end in a po
tendon coming down to the adductor tubercle (fig. 1143). This replaces here the medial
muscular septum, and the insertion of the tendon marks the level of the lower epiphysis
of the femur. At the lateral and back part of the thigh the vastus lateralis is separated fro
biceps by a groove which indicates the lateral intermuscular septum. Of these septa, pro
tions inward from the fascia lata to the linea aspera, the lateral lies between the vastus la
and the biceps. It reaches from the lateral tuberosity of the femur to the insertion
gluteus maximus. Just above the condyle it is perforated by the superior lateral articul
sel and nerve. The medial septum extends from the adductor tubercle to the trochante
is weak in comparison, and separates the adductor from the vastus medialis. A thir
weakest of all, separates the adductor and the hamstrings. The fascia lata has the same
as that in the neck in causing pus to burrow, especially downward, and in rendering the di
sis of swellings beneath it difficult. Thickest above and on the lateral aspect, and again
the bony prominences at the knee-joint, at both of which sites it receives accessions
muscles, it is divided into iliac and pubic portions. The former is attached behind to s
and coccyx, iliac crest and the inguinal ligament, terminal line and pubic tubercle. E
blends with the pubic portion, which is connected with the pubic arch. At the fossa
(saphenous opening) the two may be said to separate, the iliac forming the upper corn
lateral falciform margin, and descending over the femoral vessels and extensors. The
much thinner, forms the medial margin of the fossa, and descends obliquely over the pec
and adductor longus behind the vessels, to blend with the sheath of the iliopsoas and caps
the hip-joint.

The inguinal (Poupart's) ligament (fig. 1142).—The abdomen is sepa
from the thigh by a fold, best marked in flexion—the inguinal furrow. In

pressure detects the meeting of the aponeurosis of the external oblique and the fascia lata, i. e., Poupart's ligament, extending between the anterior superior spine of the ilium and the tubercle (spine) of the pubis. The line representing it should be drawn slightly convex downward, owing to the attachment of the deep fascia. It forms the base of the femoral trigone; its medial attachment blends with the triangular lacunar (Gimbernat's) ligament. The parts passing under the inguinal ligament and their arrangement have been given at p. 1399, fig. 1109).

The **femoral trigone** (**Scarpa's triangle**) (figs. 1142, 1143).—Immediately below the inguinal ligament a hollow is seen corresponding to this region, the

FIG. 1142.—SUPERFICIAL DISSECTION OF THE FRONT OF THE THIGH.
(Hirschfeld and Leveillé.)



lateral and medial boundaries of which are brought into view when the limb is raised, the adductor longus especially when the limb is abducted, and the sartorius when the thigh is flexed and the limb extended and rotated laterally. The floor of the femoral trigone is not horizontal, the plane of the medial part being very oblique. It is formed lateromedially by the iliopsoas, pectineus, adductor brevis (slightly), and adductor longus.

A **psoas abscess** descending below the inguinal ligament usually does so on the lateral aspect of the femoral vessels; if the sheath gives way, or if the abscess follows the profunda artery, it will pass beneath the adductor longus and point toward the medial side of the thigh. (Taylor.) If it simulate a femoral hernia, examination of the back and the fact that the swelling is below the fossa ovalis will prevent mistakes. Three **nerves** come into the thigh between the pelvis and Poupart's ligament, i. e., the lumboinguinal (genitocrural) in the femoral sheath, the femoral (anterior crural) between the iliacus and psoas and the lateral femoral cutaneous close to the lateral attachment of the inguinal ligament.

The **obturator nerve** divides into two in the obturator foramen, the two divisions being separated by some fibers of the obturator externus, and lower down by

the adductor brevis (fig. 1143). The relations, course, and distribution

ally in the base of the trigone, the inguinal lymphatic nodes can be detected
thin person (fig. 1153)

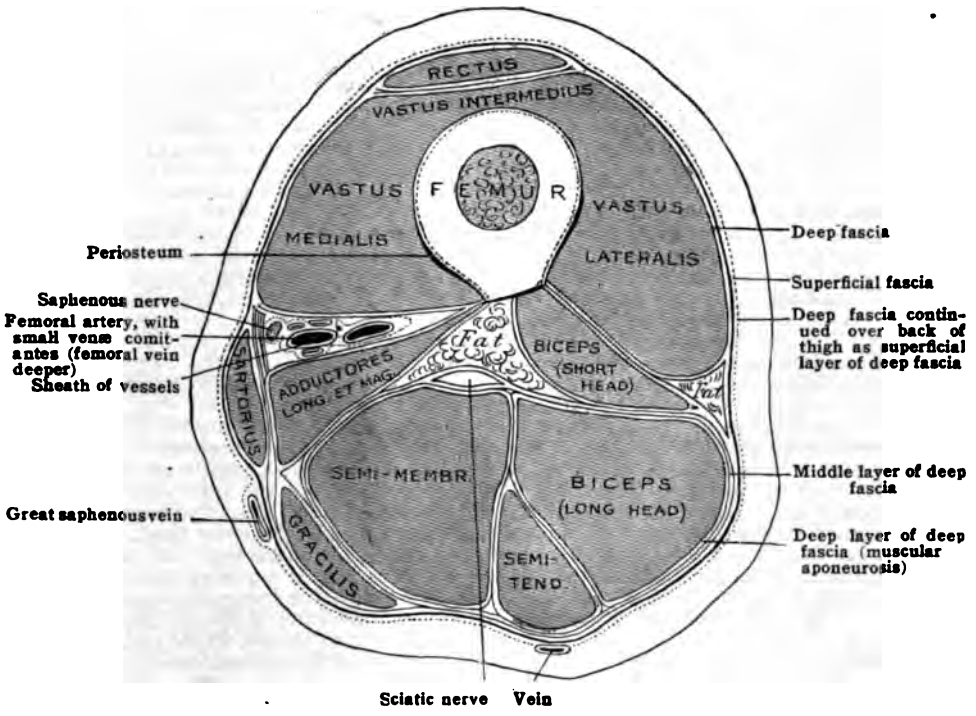
The fossa ovalis (saphenous opening).—The depression corresponding to
is placed just below the lacunar (Gimbernat's) ligament, with which its upper
tremity blends. Its center is about 3.7 cm. (1½ in.) below and also lateral
line dropped vertically from the pubic tubercle. This and the other structu
concerned in femoral hernia are fully described under this section (p. 1398).
course of the great saphenous vein is given below, p. 1454.

Line of femoral artery.—A line drawn from the midpoint between the ante
superior spine and the symphysis pubis to the adductor tubercle will corresp
with the course of this vessel. The sartorius usually crosses it 10 cm. (3 to 4 i

below the inguinal (Poupart's) ligament. The profunda artery arises usually 3.7–5 cm. (1½ to 2 in.) below Poupart's ligament.

The incision for tying the femoral in the femoral trigone should be about 7.5 cm. (3 in.) long, in the line of the artery, and begins about 7.5 cm. (3 in.) below the inguinal ligament, and runs over the apex of the triangle. The femur is flexed slightly, abducted and rotated laterally. The fascia lata being divided, the sartorius, readily recognized by its direction, is drawn laterally. The closely subjacent sheath must be opened on its lateral side. Structures that may be seen are a vein joining the great saphenous, the anterior cutaneous, saphenous nerve, and that to the vastus medialis. The *collateral circulation* (fig. 1140) is mainly through the following channels:—(1) The lateral and medial circumflex above, with the genu suprema and lower muscular branches of the femoral, and the articular of the popliteal. (2) The perforating branches of the profunda above, with the vessels below first given. (3) The comes nervi ischiadici with the articular of the popliteal. Ligature of the femoral artery and vein results in gangrene in 36 to 39 per cent. of cases (Kagiyama).

FIG. 1144.—SECTION OF THIGH THROUGH UPPER PART OF HUNTER'S CANAL. (W. A.)



The **femoral vein** below the inguinal ligament lies immediately to the medial side of the artery. From this point on the vein gets to a somewhat deeper plane, though still very close to the artery, and gradually inclining backward, lies behind its companion at the apex of the triangle, and below lies somewhat laterally to it.

From the apex of the femoral trigone (Scarpa's triangle) a depression runs down along the medial aspect of the thigh, corresponding to the groove already mentioned between the vastus medialis muscle and the adductors. Along this groove lies the sartorius, and beneath it the **adductor (Hunter's) canal,** a triangular intermuscular gap with its apex toward the linea aspera, and its base or roof formed by the fibrous expansion which ties together its boundaries, viz., the adductor longus and magnus and the vastus medialis (fig. 1144).

The vein, which in the upper part of the canal lies behind the artery, separating it from the three adductors, lower down inclines more and more to the lateral side. The saphenous nerve lies also in the canal, but not in the sheath. The above-mentioned space terminates at about the junction of the middle and lower thirds of the thigh, in the opening in the adductor magnus by which the artery enters the upper and medial part of the popliteal space. The saphenous, the largest branch of the femoral nerve, having crossed the femoral vessels lateromedially, accompanies them as far as the opening in the adductor magnus. Here it perforates the aponeurotic roof, and is prolonged under the sartorius, accompanied by the superficial part of the genu suprema artery, to perforate the fascia lata between the sartorius and gracilis, and run with the great saphenous vein at the upper and medial part of the leg.

Pressure may be applied to the femoral artery—(1) Immediately below the inguina ment, where it should be directed backward so as to compress the vessel against the brim pelvis and the capsule of the hip-joint; (2) at the apex of the femoral trigone, the pressur being directed laterally and a little backward, so as to compress the vessel against the (3) in the adductor canal the pressure should be directed laterally with the same object. must be taken, especially above, to avoid the vein, which lies very close to the artery, an the femoral nerve, which enters the thigh about 1.2 cm. ($\frac{1}{2}$ in.) lateral to the artery, and s breaks up into its branches, superficial and deep.

In **ligature of the femoral artery in Hunter's canal,** the line of the incision, in the r third of the thigh, must exactly follow that of the vessel. It is frequently made too l exposing the vastus medialis. Branches of the saphenous vein being removed, the fasci is slit up and the sartorius identified by its fibers descending medially. Those of the medialis are less oblique and are directed downward and laterally. The sartorius havin drawn to the medial side, usually, the aponeurotic roof of the canal is opened, and the fe sheath identified. The vein, here posterior and to the lateral side, is closely connected artery. The saphenous nerve and the nerve to the vastus medialis are superficial to the and should be avoided.

The close contiguity of the femoral artery and vein accounts for the comparative freq of arteriovenous aneurysms especially in the upper part, where the vessels are easily wo Their superficial position here further accounts for the facility with which malignant di e. g., epitheliomatous glands, may cause fatal hemorrhage.

The femur.—Access to the femur is best attained on the lateral side of the shaft along t of the lateral intermuscular septum (fig. 1144), the biceps being pulled backward, and the lateralis detached anteriorly. On the medial side the bone may be exposed by an incision ing from a point midway between the medial margin of the patella and the adductor tubere passing obliquely upward and laterally, but the parts here are more vascular. **Fractures** shaft usually occur about the center. The main tendency to displacement is of the lowe ment upward by the ham-strings. The upper fragment is displaced anteriorly in fra through the middle of the shaft. In fractures below the lesser trochanter—i. e., throu upper third of the femur the upper fragment will be flexed, abducted and rotated lat In the lower third the forward curve of the femur and its more superficial position expla fact that it is here that compound fractures of the femur may, occasionally, occur. **Os tion.**—The unstable nature of the tissues about the upper epiphysis, which appears at the the first year and unites about eighteen, and the frequency of tuberculous disease in early li well known. In the lower epiphysis ossification begins before birth, a point of medic importance in deciding whether a newly born child has reached the full period of uterine gest From this epiphysis, the level of which is denoted by a line drawn horizontally laterally fro adductor tubercle, and the vascular growing tendon of the adductor magnus—the origin exostosis is not uncommon. **Displacement of this epiphysis** (it unites about twenty) in bo and adolescence is a grave injury from the immediate risk of the popliteal vessels. The mi is usually done by overextension of the leg, as when this is caught in a rapidly moving car wheel; the epiphysis is carried forward in front of the diaphysis, the lower end of wh directed backward, endangering the vessels which are posterior and closely adjacent.

Amputation through the thigh.—This is usually performed in the lower third, by an and posterior flaps, the former being the longer, so as to ensure a scar free from pressure circular division of the muscles, vessels, and nerves. The vessels requiring attention a femoral, which lie at the medial side, and more posteriorly, the lower the amputatio descending branch of the lateral circumflex, and the termination of the profunda ne linea aspera. The femoral artery has a marked tendency to retract in the adductor Care should be taken not to include the saphenous nerve when the femoral vessels are tied to cut the sciatic cleanly and high up. When amputation has to be performed in the third of the thigh, the tendency of the iliopsoas to flex the shortened limb and thus bri sawn femur against the end of the stump must be remembered, and met by keeping the p propped up and the stump as horizontal as possible. Some of the structures now divide shown in figs. 1144, 1145).

The buttocks. Bony landmarks.—The finger readily traces the whole line of the iliac crest. Behind, it terminates in the posterior superior iliac sp which corresponds in level to the second sacral spine and the center of the sa liac joint. (Holden.)

The second sacral spine marks the lowest limit of the subdural sac and the cerebro fluid; it also corresponds to the upper border of the great sciatic notch. The first piece coccyx corresponds to the spine of the ischium. (Windle.) Its apex is in the furrow just b the lower part of the rectum.

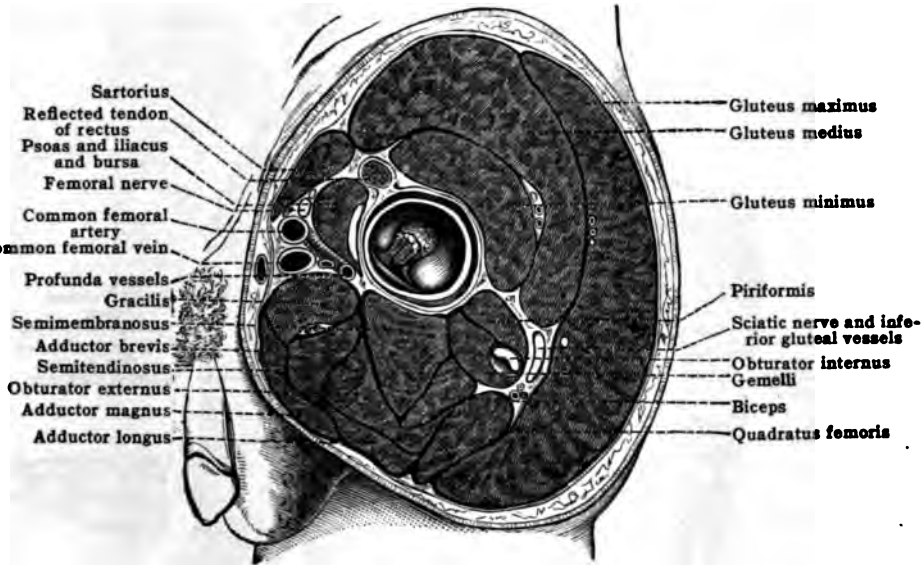
The **tuberosities of the ischium** are readily felt by deep pressure on either side of the In the erect position they are covered by the lower margin of the **gluteus maximus.** In s they are protected by tough skin, fasciæ, with coarse fibrous fat, and often by a bursa kn according to the occupation of the patients in whom it becomes enlarged, as weaver's, c man's, lighterman's or drayman's bursa. The skin of the buttock is coarse and diffic cleanse satisfactorily. The abundance of sebaceous glands accounts for the frequency of here.

Gluteus maximus.—The 'fold of the buttock' does not correspond to lower margin of this muscle. Thus, medially, it lies below the lower margi the muscle, as it runs laterally it crosses it, and comes to lie on the muscle. fold is really due to creasing of the skin adherent here to the coarsely fibro-f

tissue over the tuber ischii during extension. But in early hip disease, in which flexion of the joint is, with wasting of the muscle, almost invariably present, the fold disappears with well-known rapidity. The prominence of the buttock is mainly due to the gluteus maximus, especially behind and below, and in less degree to the other two glutei in front. Under the lower edge of the gluteus maximus the edge of the sacrotuberous (great sacrosciatic) ligament can be felt on deep pressure.

To mark out the upper border of the **gluteus maximus** a line is drawn from a point on the iliac crest 5 cm. (2 in.) in front of the posterior superior spine, downward and laterally to the back of the great trochanter. The lower border is marked out by a second line drawn from the side of the coccyx parallel with the former, and ending over the linea aspera at the junction of the upper and middle thirds of the thigh. It must be remembered that only the lower and internal fibers of the muscle are inserted into the gluteal ridge on the femur. The greater part of

FIG. 1145.—SECTION THROUGH THE HIP-JOINT AND GLUTEAL REGION. (×⅓.)



it is inserted into the fascia lata and iliotibial band and so into the lateral condyle of the tibia. Weakness of the gluteus maximus and tensor fasciæ latæ, with consequent laxity of the iliotibial band, gives rise to abnormal side-to-side passive mobility at the knee-joint in full extension.

Nerves and vessels.—The following **superficial nerves** can be marked in over the buttock (fig. 1163).

Behind the great trochanter, branches of the lateral femoral cutaneous; coming down over the crest, the lateral cutaneous branch of the last thoracic (about in a line with the great trochanter), and behind this the lateral branch of the iliohypogastric. Two or three offsets of the posterior primary branches of the lumbar nerves cross the hinder part of the iliac crest at the lateral margin of the sacrospinalis. Two or three twigs from the posterior divisions of the sacral nerves pierce the gluteus maximus close to the coccyx and sacrum, and ramify laterally. Finally, over the lower border of the gluteus maximus, turn upward branches of the posterior cutaneous (small sciatic) and its perineal branch (inferior pudendal), and the fourth sacral nerve.

Sciatic nerve (fig. 1146).—The point of emergence below the gluteus maximus and the track of this nerve (fourth and fifth lumbar and first three sacral nerves) will be given by a line drawn from a point a little medial to the middle of the space between the great trochanter and the tuber ischii to the lower part of the back of the thigh, where it usually divides into the tibial and common peroneal (internal and external popliteal) nerves.

To stretch the nerve, an incision about three inches long is made in the line of the nerve, beginning about 3.7 cm. (1½ in) below the gluteus maximus. The long head of the biceps which covers the nerve trunk and which is descending mediolaterally, is drawn medially. If the nerve is exposed lower down, the interval between the hamstrings is identified and these muscles drawn aside. The perineal branch of the posterior cutaneous (inferior pudendal) perforates the deep fascia about 2.5 cm. (1 in.) in front of the tuber ischii, and turns forward to supply the genitals.

bone after fracture, is a ready explanation of the difficulty of ensuring bony union here. (Macewen.) The patella is separated from the tibia by a pad of fat and a deep bursa, save at its insertion. Owing to the lowest part of the patella being thus separated from the joint by fat, fracture here does not, necessarily, open the joint.

FIG. 1147.—KNEE-JOINT AS SHOWN BY THE RÖNTGEN-RAYS, ANTEROPOSTERIOR VIEW. Epiphyses of the femur, tibia and fibula are visible. (Cf. fig. 261.)

The bone has the following *relation to the femur* in different positions:—(1) In **extension,** the **patella rises** over the condyles, and in full extension only the lower third of its articular surface **rests upon** that of the condyles; its upper two-thirds lies upon the bed of fat which covers the **lower** and front part of the femur. (2) In extreme **flexion,** as the prominent anterior surface **of the condyles affords** leverage to the quadriceps, the patella needs to project very little; thus, **only its upper** third is in contact with the femur, its lower two-thirds now resting on the pad of **fat between** it and the tibia. (3) In **semiflexion** the middle third of the patella **rests upon the most prominent** part of the condyles. (Humphry.) While the bone now affords **the greatest**

amount of leverage to the quadriceps, it is also submitted to the greatest amount of strai this muscle, which is acting almost at a right angle to the long axis of the patella. This p may therefore be called the 'area of danger,' as, in a sudden and violent contraction, the may be snapped across by muscular action, aided by the resistance given by the condy the same way as a stick is snapped across the knee. The amount of separation of the fra in a fracture of the patella is due chiefly to the extent to which the lateral tendinous exp of the vasti are torn; to a less degree to the hemorrhage from the numerous articular (p. 1448) and synovial effusion. The lower fragment is usually the smaller, and its fra surface tilted forward; that of the upper one usually looks backward.

The patella, the largest of the sesamoid bones, ossifies by a center which appears fr third to the fifth year. The process is completed about puberty. The rareness with necrosis and caries occur here, when the exposed situation of the bone is remembered, is explained by the density of its tissue, especially in front, and the intimate blending of the fibers with its periosteum. When the knee-joint is bent, the trochlear surface of the fem be made out, with some difficulty, underneath the quadriceps expansion. The upp lateral angle of this surface forms a useful landmark (Godlee) as a line drawn from it adductor tubercle marks the level of the lower epiphysis of the femur.

Dislocation of the patella.—The following anatomical facts account for this taking much more frequently laterally:—(1) The medial edge of the patella is more prominer thus more exposed to injury; it is also well supported, as is seen when, the parts being r the fingers are insinuated beneath each border. (2) The pull of the extensor upon the p ligamentum patellæ, and tibia is somewhat laterally, as the tibia is directed a little la to the femur, to meet the medial direction of this bone; the femora being directed medially to bring the knee-joints nearer the center of gravity, and, so, counterbalance their wide s tion above at the pelvis. The lateral pull of the quadriceps upon the patella is, in all n action of the muscle, counteracted by the space taken in the trochlear surface by the l condyle, this being wider and creeping up higher, and having a more prominent and thu tective lip. In violent contraction, however, these counteracting points may be overcor

The condyles of the femur and tibia.—It should be noted that on the m side the prominence of the medial epicondyle of the femur is well marked that of the tibia is less so, while on the lateral side this condition is reve Descending to the lateral condyle of the tibia, the iliotibial band of the f lata can be traced. The more distinct lateral condyle is a good landmar opening the joint in amputation and excision. It also indicates the lower of the synovial membrane of the knee-joint.

Farther back are the biceps and fibular collateral (long external lateral) ligament. Th on the medial side between the femoral and tibial condyles is the place for feeling for a disp medial meniscus (fibrocartilage) in 'internal derangement' of the knee, and also for 'lippi suspected osteoarthritis. On each femoral epicondyle, posteriorly, in a thin subject, can h its tubercle, which gives attachment to the collateral ligament. Owing to their being p behind the center of the bone, these ligaments become tight in extension. On the uppe posterior part of the medial femoral epicondyle the adductor tubercle and the vertical tend the adductor magnus can be felt during flexion. This bony point is a guide to the lowe physis, the ossification of which and its occasional exostosis have been mentioned. The m aspect of this epicondyle faces practically in the same direction as the head of the femur.

A *sesamoid bone* is frequently found in the lateral head of the gastrocnemius poster the joint. The X-ray shadow cast by such a bone has occasionally been interpreted floating cartilage.

Ligamentum patellæ and tuberosity of tibia.—These, in a well-formed should, with the center of the ankle-joint, be all in the same straight line, a us point in the adjustment of fractures. (Holden.) Behind the upper half of ligament is the infrapatellar pad of fat; below, the lower half is separated f the tibia by a deep bursa. The tuberosity (tubercle) of the tibia is on a level the head of the fibula.

Occasionally, the ligamentum patellæ pulls upon the tuberosity of the tibia to such a tent that the epiphyseal cartilage becomes greatly widened. The tuberosity may even be rated. This widening of the cartilage is associated with marked pain and enlargement o tuberosity.

Prepatellar bursa.—This usually protects the lower part of the patella and upper pa the ligamentum patellæ. It is liable to be enlarged in those who habitually kneel much enlargement being either fluid or solid, and occasionally, in tertiary syphilis. Its close con tion with the patella and, at the sides, with the joint itself, is to be remembered in infe inflammations of the bursa. Usually the deep fascia, passing off from the sides of the pa upward to the thigh and downward to the leg, serves to conduct inflammation away from joint.

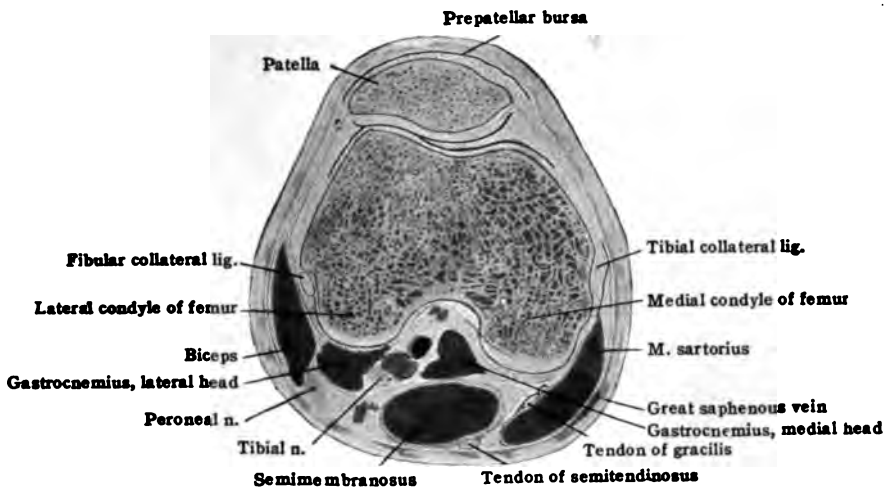
Synovial membrane (fig. 1149).—This, the largest of the synovial membra forms a short *cul-de-sac* above the patella, between the quadriceps extensor the front of the femur, this process reaching about 2.5 cm. (1 in.) above trochlear surface of the femur. At its highest point this ***cul-de-sac*** communic

with another synovial, bursa-like sac lying between the quadriceps and front of the femur. Thus, synovial membrane will usually be met with 6.2 cm. (2½ in.) or more above the trochlear surface or the upper border of the patella when the limb is extended. Flexing the joint draws the membrane down very slightly.

During extension, the above pouch is supported by the articularis genu (subcrureus). Traced downward, the membrane reaches the level of the head of the tibia, being separated in the middle line from the upper part of the ligamentum patellæ by fat. It here gives off to the intercondyloid notch the patellar synovial fold (ligamentum mucosum), with its free lateral prolongations, the alar folds (ligamenta alaria). These three so-called ligaments contain fat, the processes not only padding gaps, but also meeting concussions.

The enlargement of these processes, under conditions not yet understood, may certainly be a cause of 'internal derangement,' and simulate a loosened meniscus. But the synovial membrane of this joint is not only the largest: it is also the most complicated, a fact accounting for the grave peril of infective arthritis, and the well-known difficulty of effective drainage and cleansing this joint. Thus 'it passes over the greater portion of the crucial ligaments, but the posterior surface of the posterior crucial, which is connected by means of fibroareolar tissue

FIG. 1148.—HORIZONTAL SECTION OF THE KNEE-JOINT. (× ½). (Braune.)



to the front of the ligamentum posticum, and the lower portions of both crucial ligaments, where they are united together, of course cannot receive a complete covering from the membrane' (Morris.)

From the above ligaments the membrane is conducted, lining the lower part of the capsule and other ligaments, to the menisci (semilunar cartilages) first over their upper surfaces to their free borders, and then along their under surfaces to the tibia. Between the lateral of these and the upper and back part of the tibia is a prolongation of the synovial membrane to facilitate the play of the popliteus tendon.

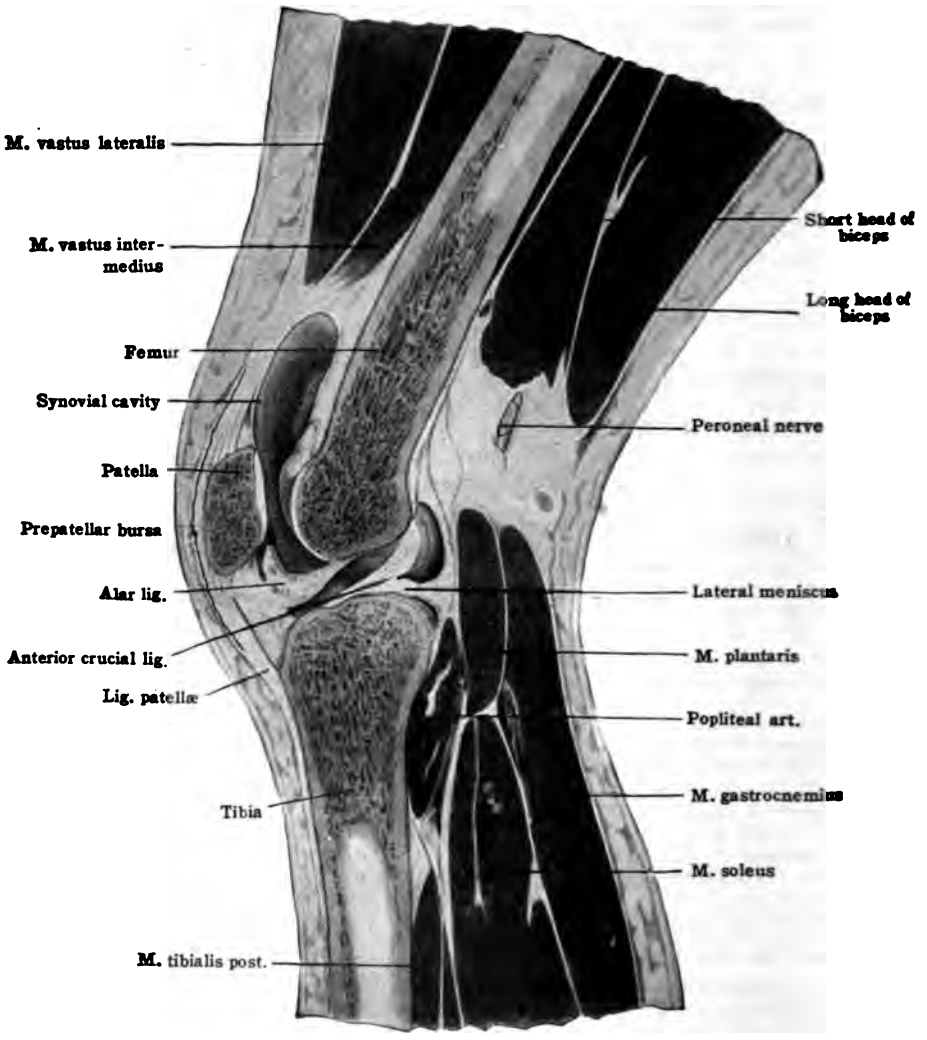
Finally, amid the complications of this synovial membrane, its communication with some of the bursæ mentioned below, and occasionally with the superior tibiofibular joint, is to be borne in mind. In effusion the bony prominences are obliterated, and the patella 'floats.' The knee-joint is easily opened by free lateral incisions lying midway between the margins of the patella and the tuberosities of the condyles.

Structures on the head of the tibia.—From before backward these are:—(1) Transverse ligament. (2) Anterior end of medial meniscus (fibrocartilage). (3) Lower attachment of anterior crucial. (4) Anterior end of lateral meniscus blending with (3). (5) Posterior extremity of lateral meniscus giving off a strong process to posterior crucial. (6) Posterior extremity of medial meniscus. (7) Posterior crucial ligament. The menisci serve as buffer-bonds and cushions between the contiguous bones.

The more frequent displacement of the medial meniscus is explained by—(*a*) its greater fixity, and, therefore, its feeling strains more. Thus, in addition to weaker attachments to the coronary and transverse ligaments, it is connected all along its convex border with the inside of the capsule, and strongly with the tibial collateral ligament. The lateral meniscus, on the other hand, is more weakly attached to the capsule, especially opposite to the popliteus tendon, and has no tie to the fibular collateral ligament. (*b*) When, in the erect position, the knee-joint is rotated laterally and slightly flexed, a common position, an especial strain is thrown upon the very important tibial collateral ligament, and from the above-mentioned connection, on the medial meniscus also.

Position of knee-joint in disease.—In inflammatory effusion, the position which accommodates the collection of fluid is one of moderate flexion, the ligaments being now m relaxed. Later on, when the ligaments are softened, the hamstrings obstinately displac leg backward, the tibia being rotated laterally by the biceps. The anteroposterior displace is always more marked than the lateral. In straightening an ankylosed joint, the resistar the shortened lateral, crucial, and posterior ligaments, and the facility with which a soft upper epiphysial line of the tibia may give way, must never be forgotten. **Erasion and exc** —The extent and complications of the synovial membrane render attention to the follc points imperative:—(1) Free exposure of the joint usually by an anterior curved incisior medial extremity of which must not damage the great saphenous vein. (2) The extent c

FIG. 1149.—VERTICAL SECTION OF THE KNEE-JOINT IN THE ANTEROPOSTERIOR DIREC (The bones are somewhat drawn apart. The synovial bursa usually present above the u synovial *cul-de-sac* is not shown.) (After Braune.)

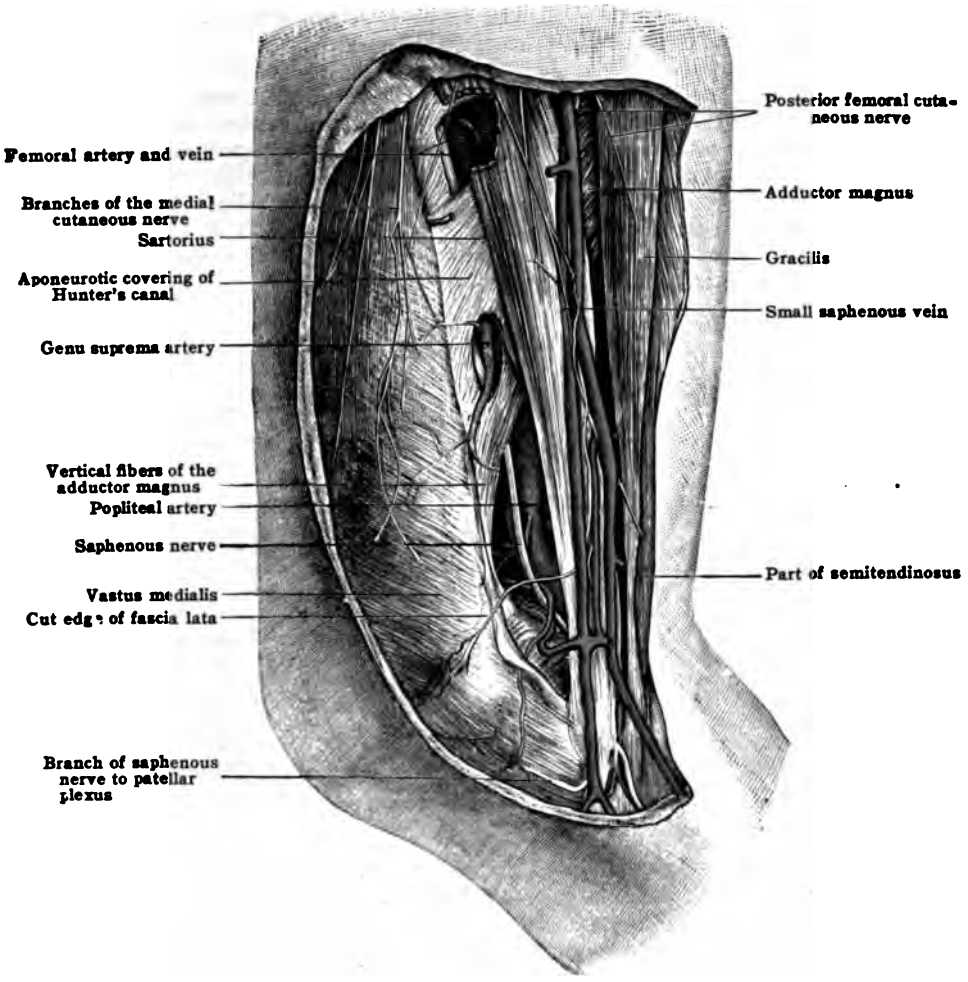


pouch under the quadriceps, it may be for 5 cm. (2 in.) above the patella, and the lateral rec under the vasti. The pouches at the back of the joint are far more difficult to deal with, the partial covering of the posterior crucial ligament, the proximity of the popliteal ar the pouches in relation to the popliteus, gastrocnemii, and back of the femoral condyles. **erasion,** the cartilage and bone, where diseased, are removed with a gouge. Owing to removal, in addition to the synovial membrane, of the menisci and crucial ligaments, and damage to lateral and patellar ligaments, there is a most obstinate tendency to flexion after In **excision,** to avoid injury to the epiphysis, the section of the femur should not pass hi than through the upper third of the trochlear surface. Of the tibia, only 12 mm. (½ should be removed.

Genu valgum.—Here the natural angle at which the femur inclines medially to the is increased. As shown by v. Mikulicz, this is due to an abnormal growth downward of medial part of the femoral diaphysis, the epiphysial line being gradually altered from on

right angles to the shaft to one which runs obliquely from without downward and medially. The femur is not only elongated on its medial side, but bent at its lower end, the concavity of the curve being lateral. Other changes have to be remembered. Pes valgus very commonly coexists, and in the tibia there may be a compensatory curve, the concavity being medial, in the lower third, or an analogous alteration in the line of the upper epiphysis may be present, its direction being no longer at a right angle with the shaft, but oblique. In Sir W. Macewen's supracondyloid osteotomy, a longitudinal incision, about 3.7 cm. (1½ in.) long is made where the following lines meet, viz., one transverse, a finger's breadth above the upper margin of the lateral condyle, and one longitudinal, 1.2 cm. (½ in.) in front of the adductor magnus tendon. The bone is divided in front of the genu suprema and above the superior medial articular artery, above the epiphysial line and behind the upward extension of the synovial membrane under the quadriceps.

FIG. 1150.—MEDIAL DISSECTION OF THE POPLITEAL REGION.
(From a dissection in the Hunterian Museum.)



The following **bursæ about the knee-joint** must be remembered. Some, it will be seen, are much more constant than others:—

A. **In front.**—(1) One between the patella and skin, the bursa prepatellaris subcutanea (fig. 1149); (2) a deeper one between the ligamentum patellæ and the upper part of the tibia; (3) between the skin and the lower part of the tuberosity of the tibia. This is not constant.

B. **On the medial side.**—(1) One between the medial head of the gastrocnemius and medial condyle, often extending between the above muscle and the semimembranosus. This is the largest of the bursæ about the knee-joint, and, after adult life, usually communicates with the knee-joint. But, owing to the narrow communication, it is rarely possible, when the parts are relaxed by flexion of the joint, to empty the cyst. For its removal a straight incision is made over the most prominent part of the swelling, its neck found by drawing aside the tendons. A ligature is then pushed high up around the neck, and the cyst cut away. (2) One superficial to the tibial (collateral) ligament, between it and the tendon of the sartorius, gracilis, and semitendinosus. (3) One beneath the ligament, between it and the tendon of the semimembrano-

sus. (4) One between the medial condyle of the tibia and the semimembranosus. (5 between the semimembranosus and semitendinosus. Of the above bursæ, the first two are constant. The second and third are often one bursa prolonged.

C. **On the lateral side.**—(1) One between the lateral head of the gastrocnemius a condyle; (2) one superficial to the fibular collateral ligament between it and the biceps t (3) one under the ligament between it and the popliteus tendon; (4) one between the po tendon and the lateral condyle of the femur. This is usually a diverticulum from the sy membrane of the knee-joint, and may enlarge to form a swelling (hygroma) in the po fossa.

The following explanations may be given of an inflamed knee-joint usually taki flexed position:—(1) By experimental injections, Braune found that the capacity of the sy sac reaches its maximum with a definite degree of flexion, i. e., at an angle of twenty-five d (2) As the same nerves supply the synovial membrane and the muscles which act up joint, reflex spasm of the flexors will help to explain the flexed position. (Hilton.)

Anastomoses around the front and sides of the knee-joint (figs. 538, 11 The most important of these take the form of **three transverse arches.** The **highest** passes through the quadriceps fibers just above the upper edge patella. It is formed by a branch from the deep division of the genu sup (anastomotica magna) and one from the lateral circumflex and superior l articular. The middle and lowest arches lie under the ligamentum patellæ. The **middle arch,** formed by branches from the genu suprema and sup medial articular on the medial side, and the inferior lateral articular, o lateral, runs in the fatty tissue close to the apex of the patella. (3) The l **arch** lies on the tibia just above its tuberosity, and results from the anasto of the recurrent tibial and the inferior medial articular. Seven arteries take place in this series of anastomoses.

POPLITEAL SPACE

The diamond-shaped popliteal space is shown in fig. 1151. In flexion hollow of this space appears; in extension it is obliterated and its boundari ill-defined the only ones now to be made out being the semitendinosus an biceps.

Popliteal tendons.—When the knee is a little bent and the foot rests on the groun following can be made out:—on the *lateral aspect*, behind the iliotibial band, and descend the prominence on the lateral side of the head of the fibula, is the tendon of the biceps. prominence also gives attachment to the fibular collateral ligament, which splits the t into two parts. Behind is the apex (styloid process) from which the posterior part fibular collateral ligament arises. Parallel and close to the medial border of the tendo peroneal nerve descends, as a rounded cord, to cross the neck of the fibula and enter the p eus longus. In tenotomy of the biceps an open incision should be employed to avoid inj the nerve and insure the division of any contracted fascial bands. On the *medial side* th dons are thus arranged: Nearest to the middle of the popliteal space is the long and more sl tendon of the semitendinosus; next, the thicker tendon of the semimembranosus; this an gracilis, which comes next, appear as one tendon, but by a little manipulation the finger c made to sink into the interval between the semimembranosus, with its thick rounded h laterally and the gracilis medially. The sartorius can easily be thrown into relief on the m side of the joint by telling the patient to raise the leg extended, the limb being rotated lat and one leg crosses over the other.

Popliteal vessels (fig. 1150, 1151, 1155).—The **artery** traverses this s from above downward, appearing beneath the semimembranosus, a little t medial side of the middle line, and then passing down in the center of the spa the interval between the gastrocnemii. Its course corresponds with a line d from the medial side of the hamstrings to the center of the lower part of the s The artery bifurcates on the level of a line corresponding to the tuberosity c tibia. It lies on the popliteal surface of the femur, the oblique popliteal liga and the popliteus. It is the second of these structures which usually pre popliteal aneurism and abscess from making their way into the joint.

The **popliteal vein,** intimately adherent to the artery, lies to the lateral side abov crosses to its medial side below. The popliteal sheath is also unusually strong. The **nerve** crosses the artery in the same direction as the vein, by which it is separated fro artery. This nerve is the direct continuation of the sciatic nerve (fig. 1151), and enter into the space than its fellow branch. The close relation of the vein and nerve explai early stiffness of the knee, the pains below, often called 'rheumatic,' and the edema, in po aneurism; also the pulsation of swellings not aneurismal.

The **superior articular arteries** (figs. 1151, 1153, 1155) course laterally and medially in ately above the femoral condyles; the way in which they cling closely to the bone here provision to prevent overstretching of the artery; the inferior one lies just above the head

fibula and below the medial condyle of the tibia. The deep part of the genu suprema artery runs in front of the tendon of the adductor magnus; the superficial with the saphenous nerve.

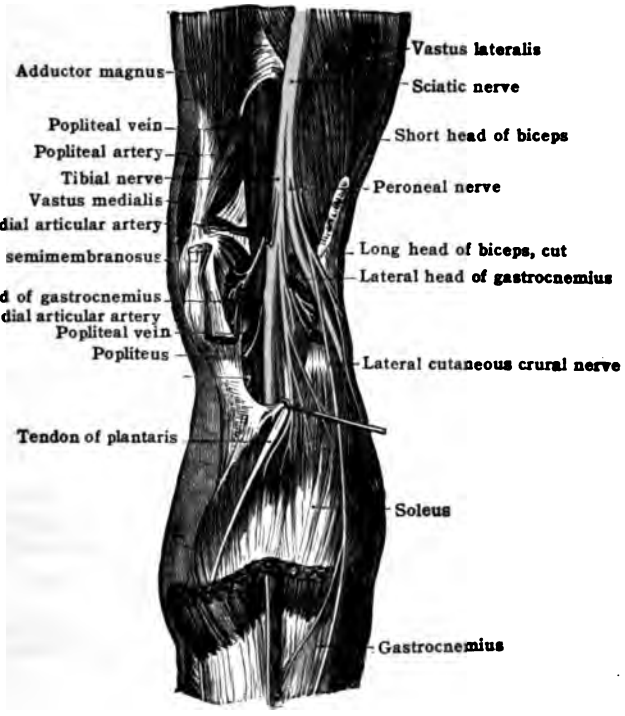
The **popliteal artery may be ligatured**—(A) **Behind,** in the upper part of the popliteal space, just after its emergence from under the semimembranosus. Here, for a short space of about 2.5 cm. (1 in.), the vessel is comparatively superficial after division of the fasciæ. The nerve is generally seen first, and, with the vein, must be drawn laterally. (B) **From the front,** at the medial side. The thigh being flexed, abducted, and rotated laterally, a free incision is made parallel and just behind the adductor magnus tendon, commencing at the junction of the middle and lower third of the thigh. The sartorius and the hamstrings are drawn backward, and the adductor magnus forward. Care must be taken of the genu suprema (fig. 1150). The space between the hamstrings and the adductor magnus being carefully opened up, the artery will be found in fatty areolar tissue. The vein and tibial nerve are on the lateral side of the vessel. The collateral circulation (fig. 1140) depends chiefly on the genu suprema.

The **small saphenous vein** perforates the roof of the popliteal space in its lower part. As a rule, it is not visible, unless enlarged.

The **popliteal nodes** are not to be felt unless enlarged.

Bursæ in the popliteal space.—These have been already mentioned (p. 1447).

FIG. 1151.—DEEP VIEW OF THE POPLITEAL SPACE. (Hirschfeld and Leveillé.)



THE LEG

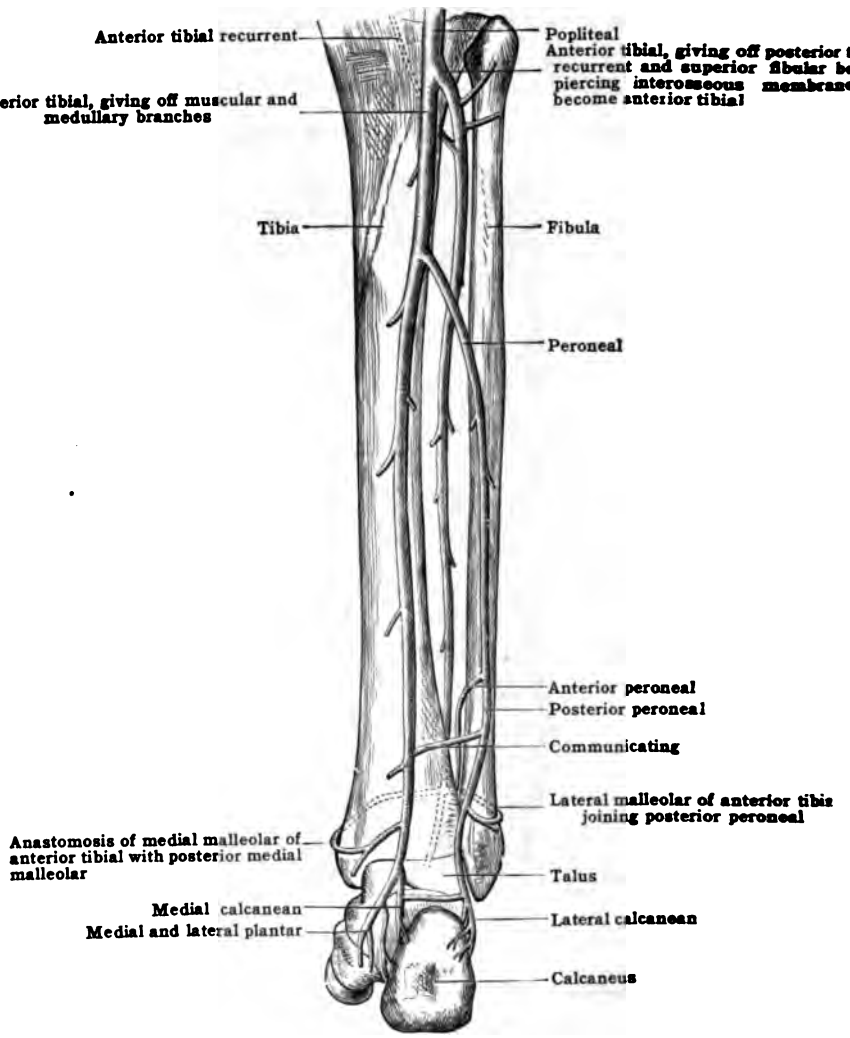
The skin.—The proneness of the skin to dermatitis in the lower third of the medial and front aspect of the leg as a result of varicose veins is well known. The close contiguity of the periosteum to the skin here accounts for the difficulty in healing chronic ulcers whose callous base has become fixed to the periosteum, and the frequency with which the upper fragment of a fractured tibia perforates the skin.

Bony landmarks.—From the *tuberosity* (tubercle) *of the tibia* descends the *anterior border* or 'shin.' This soon becomes sharp, and continues so for its upper two-thirds; in the lower third it disappears, to be overlaid by the extensor tendons. It is curved somewhat laterally above and medially below. The *medial border* can also be felt from the medial condyle to the medial malleolus. Between these two borders lies the *medial surface,* subcutaneous save above, where it is covered by the three tendons of insertion of the gracilis and semitendinosus and sartorius. The tibia is narrowest and weakest at the junction of the middle and lower thirds, the most common site of fracture. Behind the *medial malleolus,* part of the groove for and the tendon of the tibialis posterior can be felt. The

head of the fibula can be felt distinctly, but the shaft soon becomes buried an muscles till about 7.5 cm. (3 in.) above the *lateral malleolus*, where the expands into a large triangular subcutaneous surface.

This lies between the peroneus tertius and the other two peronei. The peroneus l overlaps the brevis, especially in the upper two-thirds of the leg. In the lower third the t tends to become anterior. Behind the lateral malleolus these tendons descend to the f a groove on its posterior border. The shaft of the fibula is placed on a plane posterior to of the tibia, and curves backward in a direction reverse to that of the tibia.

FIG. 1152.—ANASTOMOSES OF TIBIAL ARTERIES.

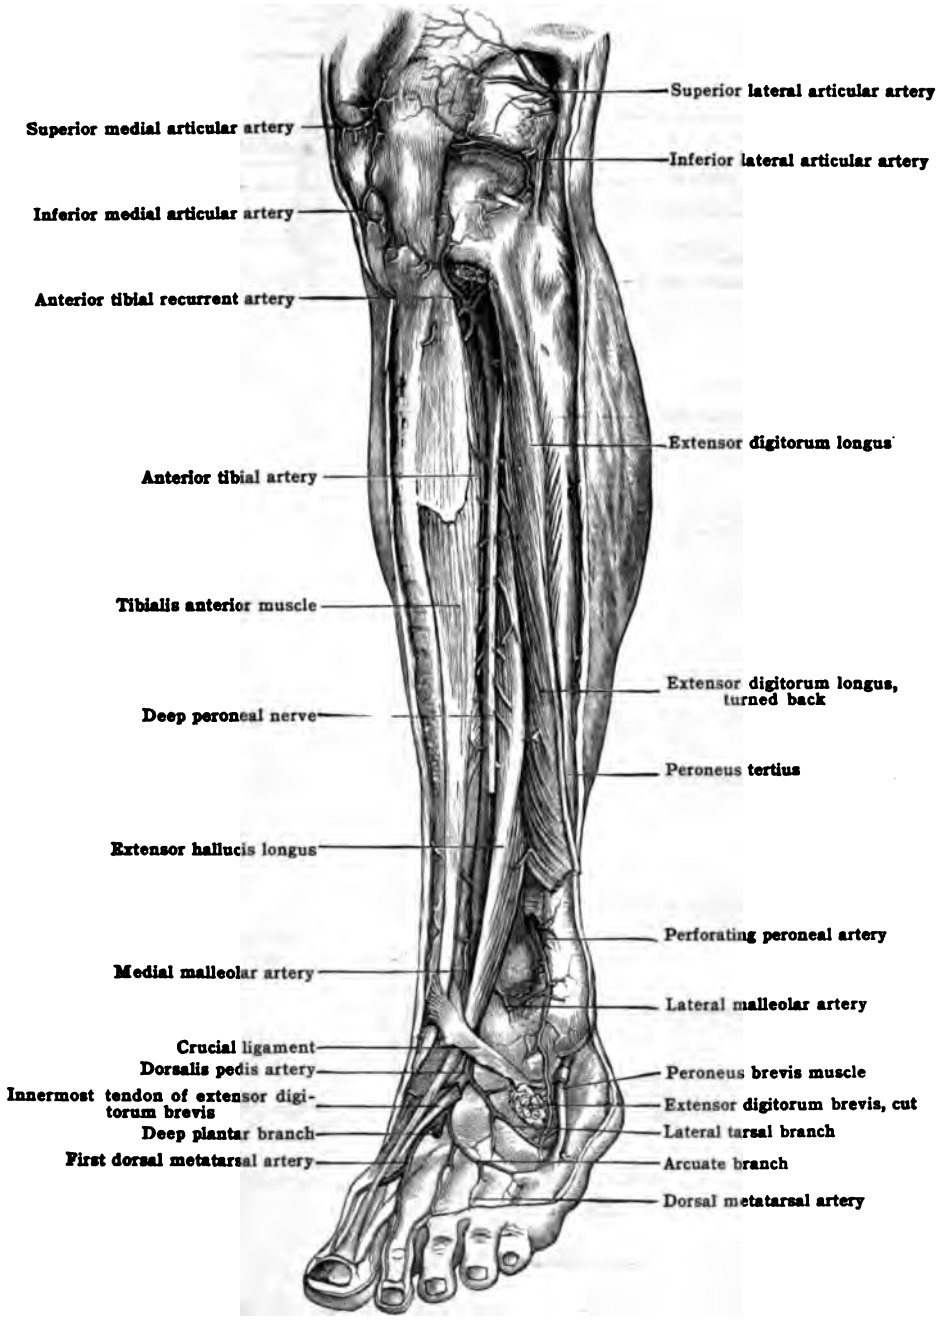


Muscular compartments and prominences.—When the muscles of the leg thrown into action by dorsiflexion and plantar flexion of the foot or by stand on the toes, several groups of muscles stand out on the surface, owing to cert compartments, and the origin of certain muscles from, and their separation the deep fascia. The bones and the two peroneal septa divide the leg into f compartments (fig. 1156).

These are, mediolaterally:—(1) A medial, corresponding to the medial surface of the t (2) An anterior, between the crest of the tibia and the anterior peroneal septum, atta to the anterolateral border of the fibula, and separating the extensors from the peronei. surface-marking would be a line from the front of the head of the fibula to the front of lateral malleolus. In this anterior compartment lie the extensor muscles and origin of peroneus tertius, and the anterior tibial vessels and nerves. (3) A lateral or peroneal c partment, lying between the anterior and posterior peroneal septa, the latter being atta to the posterolateral border of the fibula, and separating the peronei from the calf and d

flexors. This peroneal compartment, a narrow one, contains the two chief peronei and the peroneal (external popliteal) nerve and its three divisions. (4) Much the largest, this, the posterior, lies between the posterior peroneal septum and the medial border of the tibia, and contains the calf and deep flexor muscles, the posterior tibial vessels and nerves, and the peroneal artery and its posterior branch.

FIG. 1153.—THE ANTERIOR TIBIAL ARTERY, DORSAL ARTERY OF THE FOOT, AND PERFORATING BRANCH OF THE PERONEAL ARTERY, AND THEIR BRANCHES.



The space between the tibia and fibula in front is mainly occupied by the fleshy belly of the tibialis anterior; lateral to this, and much less prominent, is the narrower extensor digitorum longus; lateral to this, again, are the peronei longus and brevis. Lower down, in an interval between the tibialis and the extensor of the toes, the extensor hallucis, here almost entirely tendinous, comes to the surface. Behind, the prominence of the calf is mainly formed by the gastrocnemius. On the patient's rising on tip-toe, the tendo Achillis starts into relief from about the middle of the leg. Of the two heads of the gastrocnemius, the medial is seen to be the

larger. On either side of the tendon, but more distinctly on the lateral side, where it is less overlapped by the gastrocnemius, the soleus comes into view. Its muscular fibers are continued on the deep surface of the tendon to within a short distance of the heel. Between the tendon and the upper part of the os calcis is a bursa, occasionally the seat of effusion, as in gonorrhea.

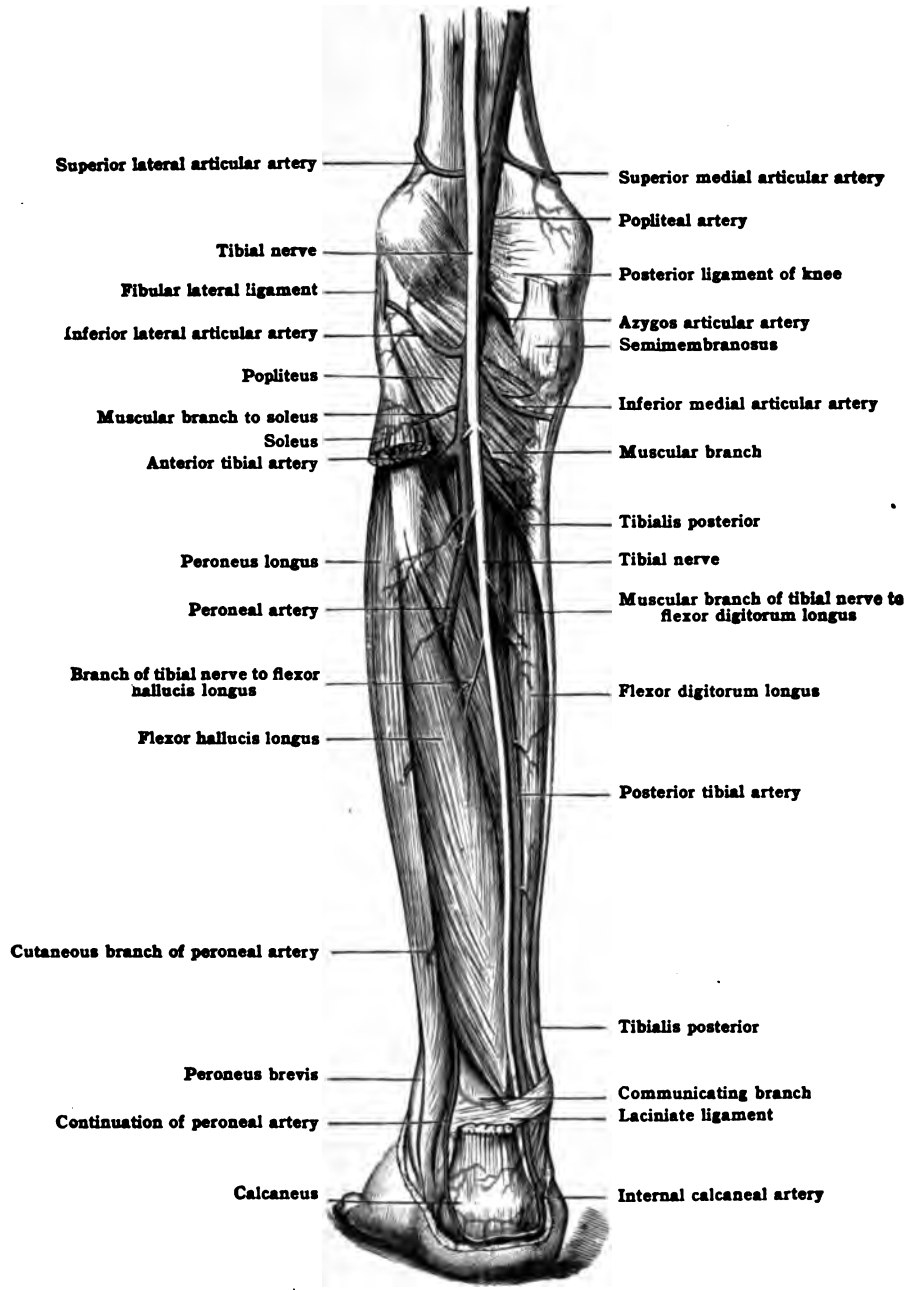
The bones.—Their relative position and curves have been mentioned (p. 1449). **Access.**—That to the **tibia** is easy along the medial aspect. The **fibula** is best explored by a free incision along the line of the posterior peroneal septum, which lies between the peronei and the muscles at the back (p. 1450). The presence of the superficial peroneal (musculocutaneous) nerve per-

forating the deep fascia in the lower third below and that of the the common peroneal (external popliteal) in relation to the neck of the fibula above, must be remembered. **Fractures.**—When, as is most frequent, the tibia gives way from indirect violence, the fracture is usually at the weakest spot, or the junction of the middle and lower thirds. The line of obliquity is generally marked, and from above downward and forward. The lower fragment, pulled upward by the powerful calf muscles, rides behind the upper, which projects forward under the skin. The

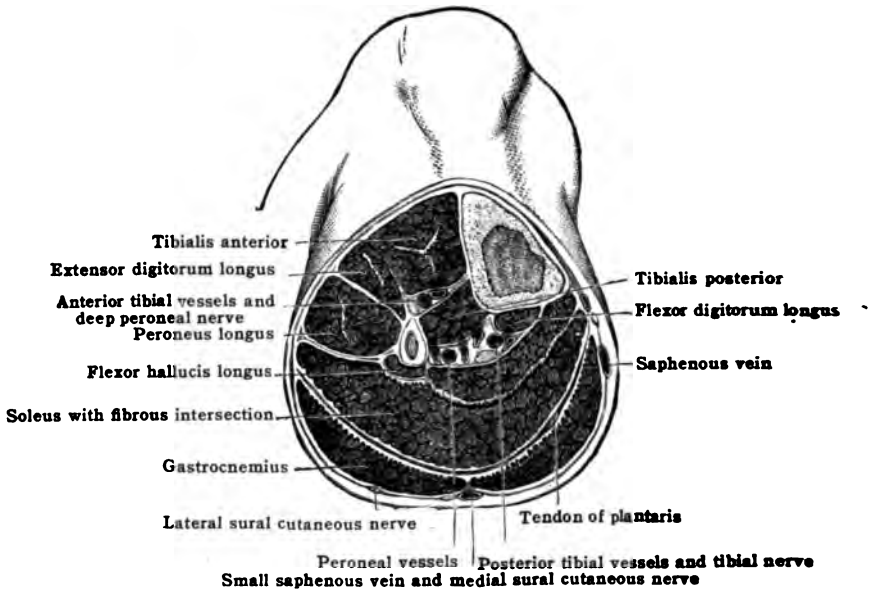
FIG. 1155.—POPLITEAL AND POSTERIOR TIBIAL ARTERIES.



fibula, bending more than the tibia, snaps at a higher level. Tenderness on pressure is the best guide here, as it is in suspected fractures of the upper tibia, transverse from direct violence. The most common variety of **fracture of the fibula** is that called after **Pott**, complicated with displacement of the foot. Here, from abduction of the foot, a severe strain is thrown upon the deltoid ligament, which gives way; the talus (astragalus) is pressed against the lateral malleolus, and the inferior tibiofibular ligaments resisting, the fibula yields 5 to 7 cm. (2 to 3 in.) above the ankle, the upper end of the lower fragment being usually displaced toward the tibia. If the deltoid ligament is strong, the strain often tears off the medial malleolus. The medial margin

of the foot is turned toward the ground, the lateral raised (pes valgus). The foot is also displaced backward. On the medial side of the ankle there is a marked projection of the lower end of the tibia; higher up, on the lateral side, a depression where the fibula is broken. The need of replacing the foot and the weight-bearing talus (astragalus) accurately, the fact that the ankle-joint is opened and the numerous tendons likely to be matted are the chief points to bear in mind. In **Dupuytren's fracture** there is not only fracture of the lower end of the fibula, but the inferior tibiofibular ligaments are now torn. The foot is displaced upward and laterally, together with the lower end of the fibula. **Epiphyses.**—The upper one of the tibia appears shortly before birth and includes the condyle and tuberosity (fig. 1147). It does not fuse with the shaft till the age of twenty or later. This fact and the powerful strain of the rectus on this epiphysis explain the obscure pain sometimes complained of in young adults much given to athletics, over the tibial tuberosity. The lower epiphysis, including the medial malleolus, appears in the second and joins about the eighteenth year. Separation here is not very uncommon up to puberty. In **osteotomy** of the tibia, simple or cuneiform, when the curve is anteroposterior as well as lateral, the close proximity of the tibialis anterior tendon to the lateral border of the crest must be remembered, and when the fibula does not yield to careful force, it, also, must be divided, or damage may be done to the superior and inferior tibiofibular ligaments, or to the epiphyses of the bones.

FIG. 1156.—UPPER SEGMENT OF A SECTION OF THE RIGHT LEG IN THE UPPER THIRD. (Heath.)



Vessels.—The **saphenous veins** should be carefully traced, owing to the tendency of these and their branches to become varicose. The **great saphenous** (figs. 1142, 1154), having passed from the arch on the dorsum over the medial malleolus, runs up close to the medial border of the tibia, where it is to be avoided in ligature of the posterior tibial, to the back of the medial condyle; here this vessel is to be remembered in operations on the knee-joint; then upward along the thigh, over the roof of the adductor (Hunter's) canal, to the fossa ovalis (saphenous opening) (p. 1438 and fig. 1154), where it joins the femoral by perforating the cribriform fascia and the femoral sheath. Four to six valves are present, chiefly in the upper part.

The 'dangerous area,' or that in which thrombosis is most likely to occur, reaches from the center of the thigh to the middle of the leg. (Bennett.) The saphenous nerve joins the vein below the knee, having been under the sartorius above this point (figs. 1143 and 1144). The surface-marking of the upper part of the vein is a line drawn from the posterior border of the sartorius or the adductor tubercle to the lower part of the fossa ovalis. The small saphenous vein passes behind the lateral malleolus, runs upward over the middle of the calf, and joins the popliteal by perforating the deep fascia in the lower part of the popliteal space. This vein is accompanied by the medial sural cutaneous (external saphenous) nerve throughout its course.

The **popliteal artery** bifurcates at the lower border of the popliteus, about on a level with the tuberosity of the tibia. About 5 cm. (2 in.) lower down the peroneal artery comes off from the posterior tibial (figs. 1152, 1155).

The course of the **posterior tibial** corresponds with a line drawn from the center of the lower part of the popliteal space to a point midway between the tip of the medial malleolus and the medial edge of the calcaneus.

In the lower third, the artery becomes more superficial, passing from beneath the calf muscles, lying between the tendo Achillis and medial border of the tibia, and covered only by the skin, deep fascia, and, lower down, by the laciniate (internal annular) ligament. It is here, in its close relation to the tendons of the tibialis posterior and flexor digitorum longus, that it is liable to be injured in the older methods of tenotomy. The nerve is medial above, lateral below (fig. 1155).

Ligature of the posterior tibial in the middle of the leg.—The following are the chief points in the technic. An incision, 7.5 to 10 cm. (3 to 4 in.) long, is made 1.2 cm. (½ in.) behind the medial border of the tibia, to avoid the trunk of the great saphenous. The deep fascia being freely opened, the medial head of the gastrocnemius is drawn backward. The tibial attachment of the soleus, thus exposed, is cut through carefully, so as to allow of identification of its central membranous tendon, which must not be confused with the deep intermuscular septum over the flexor. Any sural vessels are now tied. The above-mentioned special septum is next made out, passing between the bones (vertical line descending from oblique line of tibia and oblique line of fibula). On division of this septum the nerve usually comes into view, the artery lying more laterally. The needle is passed from the nerve; the venæ comitantes may be included. The muscles should now be fully relaxed by flexion of knee and plantar flexion of foot. The ligature will be placed below the peroneal artery. The posterior tibial in its upper part may also be ligated through a straight incision down the middle of the leg posteriorly. Ligation of the posterior tibial is followed by gangrene in a large percentage of cases.

The course of the **anterior tibial artery** corresponds with a line drawn from a point midway between the lateral condyle of the head of the tibia and the head of the fibula to one on the center of the ankle-joint.

This line corresponds to the lateral border of the tibialis anterior and the interval between it and the extensor digitorum longus (figs. 1152, 1153). This is shown when the first of these muscles is thrown into action. The accompanying nerve is in front in the middle third of the leg, lateral above and below.

Ligature of the anterior tibial artery at the junction of the upper and middle thirds of the leg. The limb being flexed and rotated medially, an incision is made, 7.5 to 10 cm. (3 to 4 in.) long, in the line of the artery, distant 2.5 cm. (1 in.) or more (according to the size of the leg) from the crest, and beginning about 5 cm. (2 in.) below the head of the tibia. If, on exposure of the deep fascia, the intermuscular septum between the tibialis and long extensor of the toes is not well defined, the fascia must be freely slit up in the line of the artery, and the sulcus felt for. A small muscular artery may lead down to the trunk. The foot is now dorsiflexed and the artery sought for deep on the interosseous membrane. The nerve should be drawn to the outer side. The venæ comitantes may be included in the ligature.

In **senile gangrene** the liability of the tibial arteries to disease and consequent thrombosis and interference with the collateral circulation accounts both for the extension of the disease and the difficulty in detecting pulsation.

The **peroneal artery** (figs. 1152, 1155) given off from the posterior tibial about an inch below the popliteus, or two inches below the head of the fibula, runs deeply along the medial border of this bone, covered by the flexor hallucis longus, the nerve to which accompanies the vessel.

It gives off the *anterior peroneal*, through the interosseous membrane, to the front of the lateral malleolus about an inch above the level of the ankle-joint. Its continuation, as the posterior peroneal, runs behind the malleolus, to join the anastomosis about the ankle-joint.

The **nutrient artery** of the tibia arises from the posterior tibial near its commencement. It is the largest of all the nutrient arteries to the shafts of long bones; that for the fibula comes from the peroneal.

As a general rule, in **amputation** 2.5 cm. (1 in.) below the head of the fibula, only one main artery—the popliteal—is divided. In amputations 5 cm. (2 in.) below the head of the fibula, two main arteries—the anterior and posterior tibials—are divided. In amputations 7.5 cm. (3 in.) below the head, three main arteries—the two tibials and the peroneal—are divided. (Holden.) (Cf. figs. 1152, 1156.) In an amputation through the middle of the leg, the anterior tibial artery would be found cut on the interosseous membrane between the tibialis anterior and the extensor hallucis longus, the deep peroneal nerve here lying in front of the vessel. The posterior tibial would be between the superficial and deep muscles at the back of the leg lying on the tibialis posterior, its nerve being to the lateral side. The peroneal would be close to the fibula in the flexor hallucis longus.

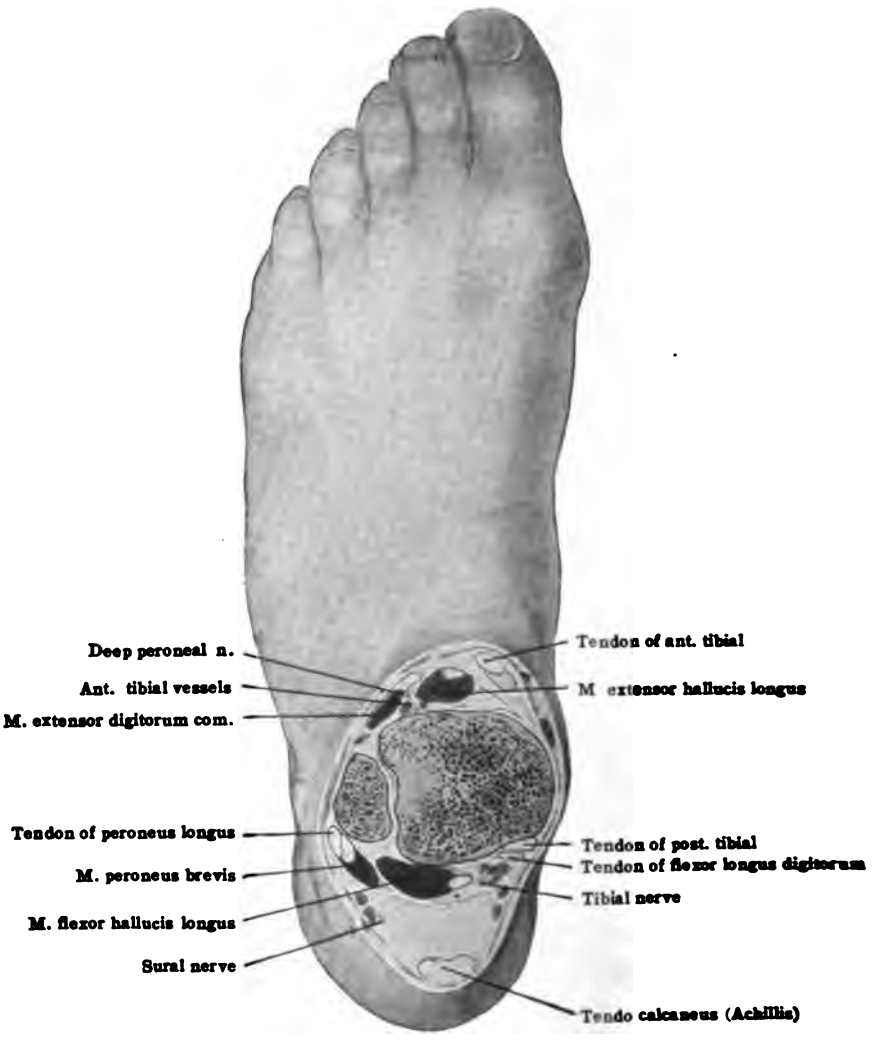
The **superficial peroneal** (musculocutaneous) nerve (fig. 1157), having passed through the peroneus longus and then between the peroneus longus and peroneus brevis, perforates the deep fascia in the lower third of the leg in the line of the septum between the peronei and extensors. Directly after, it divides into its two terminal branches.

Amputation of the leg.—To give one instance only, amputation at the seat of election, or a hand's-breadth below the knee-joint, will be alluded to. The above name was given because the pressure of the body is well carried on the prominences about the knee-joint, especially the tuberosity of the tibia, when the patient walks with the knee flexed on a "bucket" artificial limb. Thus the scar, being central, is here not of importance. Two broadly oval lateral flaps of skin and fasciæ are raised, and the remaining soft parts severed down to the bones with circular sweeps of the knife. In sawing the bone, the smaller size of the fibula and its

subperiosteally, leaving the tip and calcaneofibular, will admit of the insertion of a tube and good drainage if the foot is so slung as to keep its lateral aspect dependent.

Tendons.—(A) **In front of ankle** (figs. 1157, 1159).—Lateromedially are—(1) The tibialis anterior, the largest and most medial. This tendon appears in the lower third of the leg, lying just under the deep fascia, close to the tibia; then, crossing over the lower end of this and the ankle-joint, it passes over the medial side of the tarsus, to be inserted into the medial and lower part of the first cuneiform and the adjacent part of the first metatarsal. (2) The extensor

FIG. 1159.—HORIZONTAL SECTION THROUGH THE LOWER PART OF THE LEG. (After Braune.)



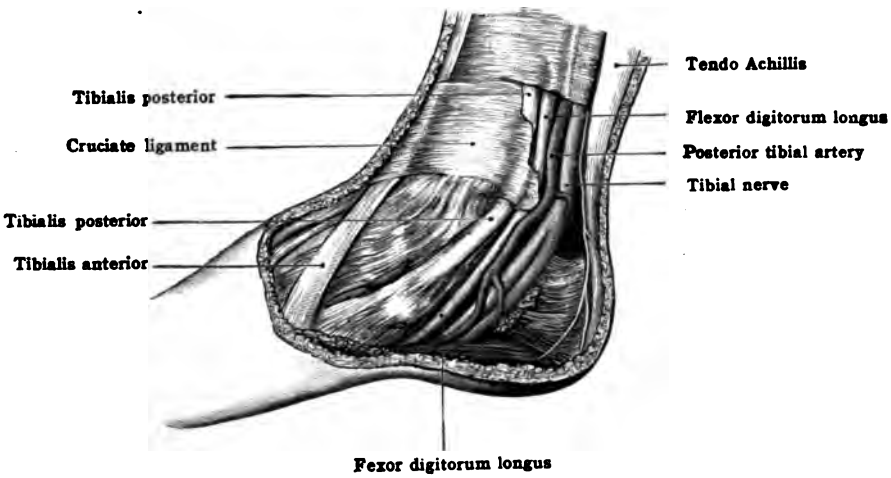
hallucis longus. This tendon, concealed above, appears low down in a line just lateral to the last, and then, crossing over the termination of the anterior tibial vessels and nerves (to which its muscular part lies lateral), it descends along the medial part of the dorsum to be inserted into the base of the last phalanx of the great toe. (3) and (4) The extensor digitorum longus and peroneus tertius enter a common sheath in the transverse crural ligament. The former then divides into four tendons, which run to the four lateral toes. The peroneus tertius is inserted into the upper surface of the base of the fifth (often also the fourth) metatarsal bone.

(B) **Behind.**—The tendo calcaneus (Achillis), the thickest of all tendons, begins near the middle of the leg, in the junction of the tendons of the gastrocnemii and, a little lower, (p. 1451) the soleus.

Very broad at its commencement, the tendon gradually narrows and becomes very thick. About 3.7 cm. (1½ in.) from the heel, or about the level of the medial malleolus, is its narrowest point. After this it again expands slightly, to be inserted into the middle of the back part of the calcaneus. The long tendon of the plantaris runs along its medial side, to blend with it or to be attached to the calcaneus. On either side of the tendo Achillis are well-marked furrows below. Along the medial, the tendon of the tibialis posterior and the posterior tibial vessels and nerve come nearer the surface. Along the lateral, the small saphenous vein (more superficially) ascends from behind the lateral malleolus.

(C) **On the medial side.**—The tendon of the tibialis posterior, which has previously crossed from the interspace between the bones of the leg to the medial side, lies behind the inner edge of the tibia above the medial malleolus, then behind this, being here under the flexor digitorum longus, the two tendons having become superficial on the medial side of the tendo Achillis. It then passes forward over the deltoid and under the laciniate (internal annular) ligament between the medial malleolus and the sustentaculum tali, and then below and close to the plantar calcaneonavicular ligament (*vide infra*), and so to its insertion, by numerous slips, into the tarsus and metatarsus, especially the tuberosity of the navicular. The tendon of the flexor hallucis longus cannot be felt. Having passed medially from the fibula, it crosses the lower end of the tibia in a separate furrow, then grooves the back of the talus, and passes under the sustentaculum tali on its way to its insertion.

FIG. 1160.—RELATIONS OF PARTS ON THE MEDIAL ASPECT OF THE ANKLE. (Heath).



The arrangement of the structures on the medial side of the ankle from above downward, and mediolaterally, is as follows (fig. 1159):—tibialis posterior, flexor digitorum longus, companion vein, posterior tibial artery, companion vein, tibial nerve, flexor hallucis longus. The tibiales posterior and anterior turn the sole medially, antagonizing the peronei. They also bear a large share in maintaining the longitudinal arch of the foot. The flexors not only act upon the toes, but aid the calf muscles in straightening the foot upon the leg in walking or standing upon tiptoe; hence the value of educating them in cases of flat-foot.

(D) **Tendons on the lateral aspect.**—The tendons of the two peronei, which arise from the fibula between the extensor digitorum longus and flexor hallucis longus, pass behind the lateral malleolus, the brevis being nearer to the bone (fig. 1159). They then pass forward over the lateral surface of the calcaneus, separated by the peroneal tubercle when present, and diverge.

The brevis—the upper one—passes to the projection at the base of the fifth metatarsal; the longus, lying below the brevis on the calcaneus, winds round the lateral border of the foot, grooving the lateral border and under surface of the cuboid. Finally, crossing the sole obliquely forward and medially, it is inserted into the adjacent parts of the first cuneiform and the back part and under surface of the first metatarsal. While in connection with the under surface of the cuboid, this tendon is covered in by a sheath from the long plantar ligament, and often contains a sesamoid bone. The two peronei evert the foot, as is seen in talipes valgus and in fracture of the lower end of the fibula; the peroneus longus aids in the support of the arch of the foot (p. 1464), and, by keeping the great toe on the ground, is important in the third stage of walking, skating, etc.

Annular ligaments and synovial membranes of tendons.—These strap bands of deep fascia, which serve to keep the above tendons in position, three in number, viz.:—

(A) **Lateral.**—This, the superior peroneal retinaculum, extends from th of the lateral malleolus to the lateral surface of the calcaneus. It keeps the peronei in place, and surrounds them behind the fibula in one sheath with a si synovial sac, which extends upward into the leg for 3.7 cm.(1½ in.), and s two processes into the two sheaths in which the tendons lie on the calcar Further on, while in relation with the cuboid, the peroneus longus has a se synovial sheath.

(B) **Medial.**—This, the laciniate ligament, crosses from the medial malle to the medial surface of the calcaneus.

Beneath the laciniate ligament are the following canals:—(1) For the tibialis post This tendon-sheath is lined by a synovial membrane extending from a point 3.7 cm. (1½ above the malleolus to the navicular. (2) For the flexor digitorum longus. The syn sheath of this tendon is separate from that of the closely contiguous tibialis posterior extends upward into the leg about as high as the sheath just given. It reaches down int sole of the foot; but where the tendon subdivides to enter the thecæ, each of these is line a separate synovial sheath. Next comes (3) a wide space for the posterior tibial vessel nerve; and, lastly, (4) a canal, like the other two, with a separate synovial sheath, for the te of the flexor hallucis longus. The lower margin of this annular ligament gives an attach to the abductor hallucis and blends with the plantar fascia. The medial calcaneal vessel nerve perforate the ligament.

(C) **Anterior annular ligament.**—This is a double structure. (1) **U (transverse crural ligament), above the level of the ankle-joint,** and tying tendons down to the lower third of the leg, passes transversely between the a rior crests of the tibia and fibula. Here is one sheath only, with a synovial m brane for the tibialis anterior. (2) **Lower, over the ankle-joint.** This band. **cruciate ligament,** is arranged like the letter ≺, placed thus. It is attached b root to the calcaneus, and by its bifurcations to the medial malleolus and pla fascia.

This arrangement of the branches of this ligament is not constant. In this, the l annular ligament, there are usually three sheaths with separate synovial membranes- most medial (the strongest in each) for the tibialis anterior, the next for the extensor hal longus, and the third common to the extensor communis and peroneus tertius. The exte digitorum brevis has a partial origin from this ligament.

Points in tenotomy and guides to the tendons.—The **tendo Achillis** should be div about 3.7 cm. (1½ in.) above its insertion, its narrowest point, which is about on a level wit medial malleolus. The knife should be introduced on the medial side and close to the ten so as to avoid the posterior tibial artery (fig. 1160).

The **tibialis anterior** may be divided about 25 mm. (1 in.) above its insertion into the cuneiform, a point which is below the level of its synovial sheath. The tendon has here dorsalis pedis on its lateral side, but separated by the tendon of the extensor hallucis lor The knife is introduced on this side.

The **tibialis posterior.**—The usual rule for dividing this tendon is to take a point 5 (2 in.) above the medial malleolus, and as accurately as possible midway between the ant and medial borders of the leg. This point will give the medial margin of the tibia, in clos position to which the tendon is lying, and is a point at which the tendon is rather farther the artery than it is below, and is also above the commencement of its synovial sheath sharp-pointed knife is used first to open the sheath freely, and then a blunt-pointed or divide the tendon. The flexor digitorum longus is usually cut at the same time.

Owing to the risk of injury to the posterior tibial vessels, the difficulty of ensuring div of the tendons, the following open method is, nowadays, superior, being more certain, and mitting of division of ligaments, e. g., talonavicular and anterior part of deltoid (syndesmot of Parker), which are always contracted in advanced talipes equinovarus. A V-shaped with its apex over the first metatarsal bone and its two limbs starting, the lower below margin of the plantar fascia on a line with the medial malleolus, the upper from a point the head of the talus, is turned backward. The plantar fascia is divided, the tibialis anter found, near its insertion, under the upper lip of the wound, the tibialis posterior and the f digitorum longus in the lower, the former close to the navicular. If necessary, the calca and talonavicular and anterior part of the deltoid ligaments can be divided also.

Peronei.—The peronei longus and brevis may be divided 5 cm. (2 in.) above the la malleolus, so as to be above the level of their synovial sheath. The knife should be inse very close to the bone, so as to pass between the fibula and the tendons. Division below lateral malleolus by a small flap is easier.

THE FOOT

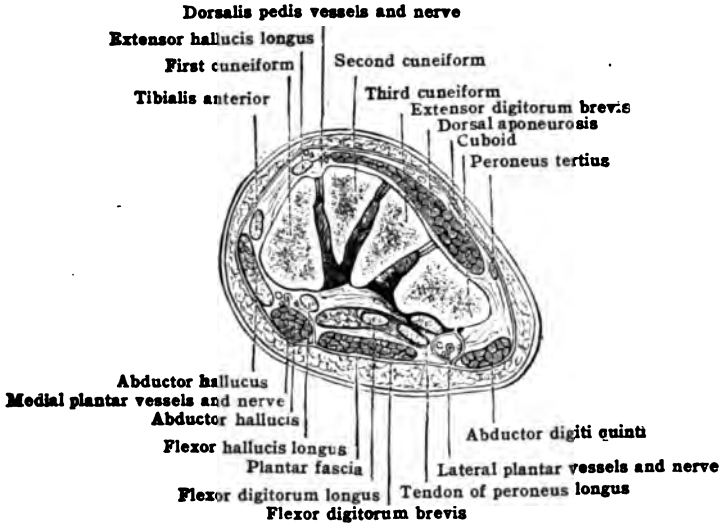
Bony landmarks.—The following are of the greatest practical importa owing to the operations which are performed upon the foot.

(A) **Along the medial aspect of the foot are the following:—**

(1) Medial tuberosity of the calcaneus; (2) medial malleolus; (3) 2.5 cm. in (1 in.) below the malleolus, the sustentaculum tali; (4) about 2.5 cm. (in front of the medial malleolus, and a little lower, is the tuberosity of the navicular, the medial guide in Chopart's amputation, the gap between it and the sustentaculum being filled by the calcaneonavicular ligament and the tendon of the tibialis posterior, in which there is often a sesamoid bone; (5) the first cuneiform; (6) the base of the first metatarsal; and (7) the head of the same bone, with its sesamoid bones below. (Holden).

(B) **Along the lateral aspect** are:—(1) The lateral tuberosity of the calcaneus; (2) the lateral malleolus; (3) the peroneal tubercle of the calcaneus (when present), 2.5 cm. (1 in.) below the malleolus, with the long peroneal tendon below it, and the short one above; (4) the projection of the anterior end of the calcaneus, and the calcaneocuboid joint, midway between the tip of the lateral malleolus and the base of the fifth metatarsal bone; (5) the base of the fifth metatarsal bone; (6) the head of this bone. The greater process of the calcaneus and the muscular origin of the short extensor lie between the peroneus brevis and tertius.

FIG. 1161.—VERTICAL SECTION THROUGH THE CUNEIFORM AND CUBOID BONES. (× ½.)



Levels of joints and lines of operations.—The line of the ankle-joint has been given at p. 1457. That of the talocalcaneal joint—the limited lateral movements of the foot take place here and at the mediotarsal joint—corresponds, on the lateral side, to a point a little in front of the lateral malleolus and midway between it and the peroneal tubercle; on the medial side, to one just above the sustentaculum tali. In **Syme's amputation** through the ankle-joint, the incision starts from the tip of the lateral malleolus, and is then carried, pointing a little backward toward the heel, across the sole to a point 1.2 cm. (½ in.) below the medial malleolus. The chief supply to the heel-flap is from the medial calcaneal. Care should be taken to divide the posterior tibial below its bifurcation and not to prick this vessel afterward.

In **Pirogoff's amputation** the incision begins and ends at the same points, but is carried straight across the sole. In each amputation the extremities of the above incision are joined by one going directly across the ankle-joint, which lies about 1.2 cm. (½ in.) above the tip of the internal malleolus.

In **Chopart's mediotarsal amputation,** which passes between the talus and the navicular on the medial side, and the calcaneus and the cuboid on the lateral, the line of the joints to be opened would be one drawn across the dorsum from a point just behind the tuberosity of the navicular to a point corresponding to the calcaneocuboid joint, just midway between the tip of the lateral malleolus and the base of the fifth metatarsal bone. The convexity of the plantar flap should reach to a point 2.5 cm. (1 in.) behind the heads of the metatarsal bones. Owing to the tendency of the unbalanced action of the calf muscles to tilt up the calcaneus and thus throw the scar down into the line of pressure, the powerful tibialis anterior tendon and those of the extensors should be carefully stitched into the tissues of the sole flap.

In **Lisfranc's (Hey's)** or the **tarsometatarsal amputation,** the bases of the fifth and first metatarsals must be defined. The first of these can always be detected, even in a stout or swollen foot; on the medial side the joint between the first cuneiform and the first metatarsal bone lies 3.7 cm. (1½ in.) in front of the navicular tuberosity. In opening the joint between the second metatarsal and the middle cuneiform, its position (the base of the former bone projecting upward on to a level 6 or 8 mm. (¼ or ⅓ in.) above the others), and the way in which it is locked in between its fellows and the cuneiform bones, must be remembered. The convexity of the plantar-flap here reaches the heads of the metatarsal bones.

These amputations are not employed as much as formerly. The introduction of th ficial limb has rendered them somewhat useless and unnecessary. They are of interest, ho in an anatomical and historical sense.

In marking out the flaps for the amputation of the great toe, the large size of the h the first metatarsal, and the importance of leaving this so as not to diminish its supp power and the treading width of the foot, and thus of marking out flaps sufficiently lo large, must be borne in mind. The dorsal incision should begin 3.7 cm. (1½ in.) above th The line of the joint is a little distal to the center of the ball of the toe (fig. 1163). Th moid bones should be left, so as not to endanger the vitality of the flaps. In amputat the other toes, the line of their metatarso-phalangeal joints lies a full inch above the we

Bursæ and synovial membranes.—The synovial sheath of the extensor lucis longus extends from the front of the ankle, over the instep, as far as metatarsal bone of the great toe. There is generally a bursa over the ins above, or it may be below, the tendon.

There is often an irregular bursa between the tendons of the extensor digitorum l and the projecting end of the talus over which the tendons play. There is much friction It is well to be aware that this bursa sometimes communicates with the joint of the head talus. (Holden.) There is a deep synovial bursa between the tendo Achillis and th caneus. Numerous other bursæ may appear over any of the bony points in the foot, espe when they are rendered over-prominent by morbid conditions. Bursæ may develop whe long continued and excessive pressure is exercised.

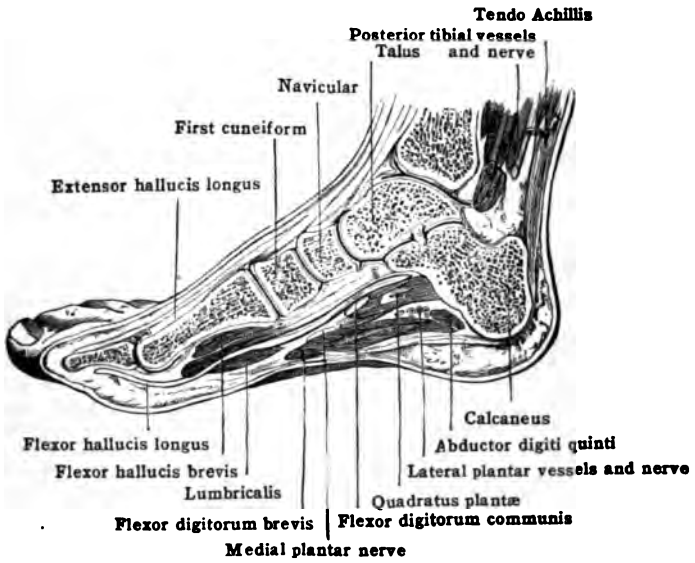
Synovial membranes.—In addition to that of the ankle-joint, there are synovial membranes in the tarsus, viz.:—(1) Talocalcaneal, peculiar to t

bones; (2) talocalcaneonavicular, common to these bones and the navicular; (3) between the calcaneus and the cuboid; (4) between the cuboid and the lateral two metatarsals; (5) between the first cuneiform and the first metatarsal; (6) a complicated and extensive one, which branches out between the navicular and cuneiform bones; between the cuneiforms; between the third cuneiform and the cuboid; between the second and third cuneiform and the second and third metatarsal bones; and between the second and third and the third and fourth metatarsal bones.

Dorsal artery.—The line of this is from the center of the ankle-joint to the upper part of the first interosseous space. On its medial side is the tendon of the extensor hallucis longus; on its lateral, the most medial tendon of the extensor digitorum longus. It is crossed by the most medial tendon of the extensor brevis. The origin of this muscle should be noted on the lateral and fore part of the calcaneus.

Cutaneous nerves (figs. 1157, 1162, 1164).—The sites of these, numerous on the dorsum of the foot, are as follows:—The **superficial peroneal (musculocutaneous) nerve,** having perforated the fascia in the lower third of the leg, divides into two chief branches, medial and lateral, which supply all the toes

FIG. 1163.—LONGITUDINAL SECTION OF FOOT. (×⅓.) (Braune.)



save the lateral part of the little, and the adjacent sides of the first and second. The **deep peroneal** becomes cutaneous in the first space, and is distributed to the contiguous sides of the above-mentioned toes. The **sural nerve** runs with the small saphenous vein below the malleolus, and supplies all the lateral border of the foot and the lateral side of the little toe. The **saphenous nerve,** coursing with the great saphenous vein in front of the medial malleolus, supplies the medial border of the foot as far as the middle of the instep. The cutaneous nerves to the sole (from the medial calcaneal, medial, and lateral plantar) are shown in fig. 1162.

Plantar arteries.—The line of the medial would be one drawn from the bifurcation of the posterior tibial, or about midway between the tip of the medial malleolus and the medial border of the heel, to the middle of the plantar surface of the great toe. The course of the lateral plantar runs in a line drawn from the bifurcation, first obliquely across the foot to a point a little medial to the medial side of the base of the fifth metatarsal, and thence obliquely across the foot till it reaches the first space and joins with a communicating branch from the dorsal artery. It thus crosses the foot twice. In the first part, it is more superficial, in the second very deep; it here forms the plantar arch, and is only separated from the bases of the metatarsals by the interossei.

The anastomosing branches about the ankle-joint are shown in figs. 1152 and 1153.

Tarsal bones.—The chief surgical points about these is the frequency with which they are diseased and their changes in talipes. **Frequency of disease.**—This is explained, chiefly, by their delicate structure and the fact that on the aspect in which they are most exposed to injury the soft parts are scanty. Disease once started, often by slight injury, finds in the terminal circulation of the parts, and the frequent want of rest, other contributing causes. The numerous and complicated synovial membranes mentioned above explain the extension of the disease. The calcaneus is the only bone in which mischief is likely to remain limited. The presence of an epiphysis to this bone appearing about the age of ten and joining at puberty is to be remembered as a starting-point of disease here. **Talipes.**—To take one instance, a case of talipes equinovarus, of congenital origin and confirmed degree, the following are the chief structural changes which should have been obviated and now have to be met, given briefly. *Calcaneus.*—This is elevated posteriorly, and rotated so that its long axis is directed obliquely medially. *Talus.*—The inclination of the neck medially is much increased, and the whole bone protruded from the ankle-joint. According to some, the neck is increased in length. *Navicular.*—This is displaced medially so that it articulates with the medial side of the head of the talus, and its tuberosity may form a facet on the medial malleolus. *Cuboid.*—The dorsal surface of this is displaced downward, and bears much of the pressure in walking. *Tendons.*—Those chiefly shortened are the tendo Achillis and those of the tibials and flexor digitorum longus. The tendo Achillis is displaced medially. *Ligaments.*—Those on the lateral side are stretched, those on the medial, especially the anterior part of the deltoid, the dorsal talonavicular and the plantar calcaneonavicular ligaments are shortened. The plantar fascia is also shortened, together with the abductor hallucis, which arises from it.

ARCHES OF THE FOOT

These are two—the **longitudinal** and the **transverse.**

(A) **Longitudinal arch** (fig. 1163).—This is by far the most important. **Extent:** From the heel to the heads of the metatarsal bones. The toes do not add much to the strength and elasticity of the foot. (Humphry.) They enlarge its area and adapt it to inequalities of the ground, are useful in climbing, and in giving an impulse to the step before the foot is taken from the ground, in the third stage of walking.

Two pillars.—The late Professor Humphry laid stress on the important differences between these two:—(1) **Posterior pillar:** This consists of the calcaneus and hinder part of the talus, viz., only two bones in order to secure solidity, and to enable the calf-muscles to act directly upon the heel, without any of that loss of power which would be brought about by many moving joint-surfaces. (2) **Anterior pillar:** Here there are many bones and joints to provide (*a*) elastic springiness, and (*b*) width. This anterior pillar may again be divided into two: (*a*) A **medial pillar,** very elastic, consisting of the talus, navicular, three cuneiforms, and three medial metatarsals. (*b*) A **lateral,** formed by the cuboids and two lateral metatarsals. This is stronger and less elastic, and tends to buttress up the medial pillar. **Keystone:** This is represented by the summit of the trochlear surface of the talus. It differs from the keystones in ordinary arches in the following important particulars (Humphry): (*a*) in not being wedge-shaped; (*b*) in not being so placed as to support and receive support from the two halves of the arch: in front the talus does fulfil this condition by fitting into the navicular; behind, it overlaps the calcaneus without at all supporting it; (*c*) this arch and the support of its keystone largely depend on ligaments and tendons; (*d*) it is a mobile keystone: to give it chances of shifting its pressure, and so obtaining rest, its equilibrium is not always maintained in one position.

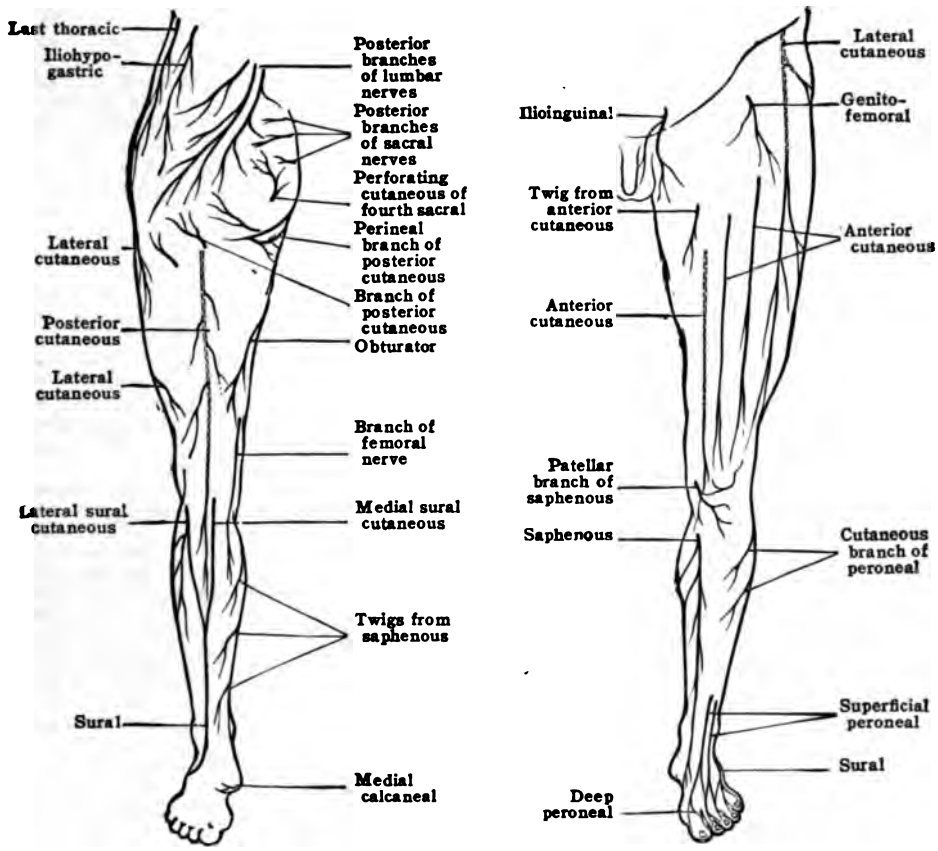
(B) **Transverse arch** (fig. 1161).—This is best marked about the center of the foot, at the instep, along the tarsometatarsal joints. This, as well as the longitudinal arch, yields in walking, and so gives elasticity and spring.

Uses of the arches.—(1) They give combined elasticity and strength to the tread. Thus they give firmness, free quickness, and dignity, both in standing and walking, instead of what we see in their absence, viz., the lameness of an artificial limb, and the shuffling or hobbling which goes with tight boots, deformed toes, flat-foot, bunions, corns, etc.; (2) they protect the plantar vessels, nerves, and muscles; (3) they add to man's height; (4) they make his gait a perfect combination of plantigrade and digitigrade, as is seen in man's walking, when he uses first the heel, then all the foot, and then the toes. (Humphry.)

Maintenance of the arch.—(1) **Plantar fascia.**—This is (*a*) a binding tie between the pillars of the longitudinal arch; (*b*) it protects the structures beneath; (*c*) it is a self-regulating ligament and protection. Thus, having a quantity of muscular tissue attached to its upper and back part, it constantly responds by the contraction of this, to the amount of any pressure made upon the foot. (2) **Plantar calcaneonavicular ligament.**—This is a thick tie-plate of fibrocartilaginous tissue, partly elastic, hence called the 'spring-ligament,' attached to the anterior margin of the sustentaculum tali and under surface of navicular. It is thickest at its medial side, where it blends with the anterior part of the deltoid ligament, and below, where the tibialis posterior

passing into the sole, is in contact with the ligament and gives much support to the head of the talus and the navicular, while it assists the power and spring of this ligament (*vide infra*). The dropping of the talus and navicular and their projection on the medial side in flat-foot are largely due to the giving way of the above ligament. (3) **Calcaneocuboid ligaments.** (*a*) **Long;** (*b*) **short.**—These ligaments are the main support of the lateral, firm, and less elastic part of the longitudinal arch. (4) **Tibialis posterior.**—The reason why this muscle has so many insertions below is to brace together the tarsal bones, and to prevent their separation when, in treading, the elastic anterior pillar tends to widen out. Of these numerous offsets, that to the navicular is the most important. Thus it strengthens the calcaneonavicular ligament by blending with it, and thus supports the arch at a trying time. By coming into action when the heel is raised, this tendon helps the calcaneonavicular ligament to support the head of the talus, and to maintain the arch of the foot when the weight of the body is thrown forward on to the instep. In other words, the tibialis posterior comes into play just when the heaviest of its duties is devolv-

FIG. 1164.—DISTRIBUTION OF CUTANEOUS NERVES ON THE POSTERIOR AND ANTERIOR ASPECTS OF THE INFERIOR EXTREMITY.



ing upon this ligament, viz., when the heel is being raised, and the body-weight is being thrown over the instep on to the opposite foot. (5) **Peroneus longus.**—This raises the lateral pillar, and steadies the lateral side of the arch. Further, by its strong process attached to the first metatarsal bone, it keeps the great toe strapped down firmly against the ground; thus, keeping down the anterior pillar of the longitudinal arch, it aids the firmness of the tread. (Humphry.) (6) **Tibialis anterior.**—This braces up the keystone of the arch. Thus, by keeping up the first cuneiform, it maintains the navicular, and so indirectly the talus *in situ*.

Fig. 1154 will remind the reader of the arrangement of the **superficial lymphatics of the lower extremity.** These follow chiefly the saphenous veins, and enter the inguinal nodes, except those from the lateral aspect of the heel, which drain into the popliteal lymph-nodes. The superficial lymphatics of the buttock enter the lateral, and those over the adductor muscles the most medial group of the inguinal glands.

The deep lymphatics of the lower limb, comparatively few in number, follow the course of the deeper vessels. After passing through some four or five glands deeply placed about the popliteal vessels (these glands also receive the lymphatics along the small saphenous vein), the lymph is carried up by lymphatics along the

femoral artery to the deep inguinal nodes; one very often occupies the femoral canal.

Fig. 1164 shows the distribution of the **superficial nerves** on both aspects of the limb.

Paralysis of the nerves of the lower extremity.—The student should take this opportunity of considering from the surgical anatomy the results of paralysis of the nerve chiefly affected, viz., the great sciatic and its branches. *Sciatic:* The limb hangs flail-like, much in the position of one affected with advanced infantile paralysis. In addition to the results of paralysis of its two divisions, flexion at the knee will be lost, owing to paralysis of the hamstrings. *Peroneal (external popliteal) nerve:* The extensors and peronei being paralyzed the foot drops, it cannot be dorsiflexed at the ankle nor abducted at the mediotarsal joint. Adduction at the latter joint is impaired owing to paralysis of the tibialis anterior. The arch of the foot is largely lost owing to paralysis of the peroneus longus. Slight extension of the two distal phalanges of the four lateral toes is still possible by means of the interossei. Sensation is impaired over the distribution of the medial sural cutaneous deep, and superficial peroneal nerves. *Tibial (internal popliteal) nerve:* Here the calf muscles, the flexors, and the muscles of the sole of the foot are paralyzed. The ankle cannot be plantar-flexed.

INDEX

In general, only nouns are indexed. Bones, Muscles, Nerves, etc. are grouped under the appropriate common headings. Boldface type indicates the more complete descriptions.
